Prologo del IMARPE

Entre las múltiples tareas de IMARPE, una de la más importantes es aquella de proveer asesoramiento científico concerniente a la pesquería industrial, basada esencialmente en el recurso anchoveta, una de las fuentes más importantes de ingreso de divisas para el Perú.

El personal científico del IMARPE y el de su predecesor, el Instituto de Investigación de los Recursos Marinos (IREMAR), han estudiado la biología, dinámica y habitat de la anchoveta, desde los inicios de los años 50. Los conocimientos obtenidos a través de estas investigaciones y los informes emitidos, han ayudado a nuestro gobierno en la formulación de regulaciones para el manejo de la pesquería pelágica durante esta turbulenta historia.

A lo largo de su historia, IMARPE ha albergado proyectos cooperativos de investigación con instituciones extranjeras y ha acogido con beneplacito a científicos del exterior. Ello ha robustecido nuestra productividad y ha coadyuvado a afianzar los contactos internacionales, sin lo cual hoy en día, no podrían conducirse investigaciones sólidas y profundas.

En los años 80, nuestro principal colaborador del exterior ha sido el personal de la Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ), con sede en IMARPE a través del Proyecto Cooperativo Peruano-Alemán de Investigación Pesquera (PROCOPA). Ellos, y sus contrapartes peruanas, han producido desde 1982 a la fecha, alrededor de 90 contribuciones sobre diversos aspectos de los recursos del sistema peruano de afloramiento (ver Apéndice II de este libro). Estamos muy complacidos con esta alta producción.

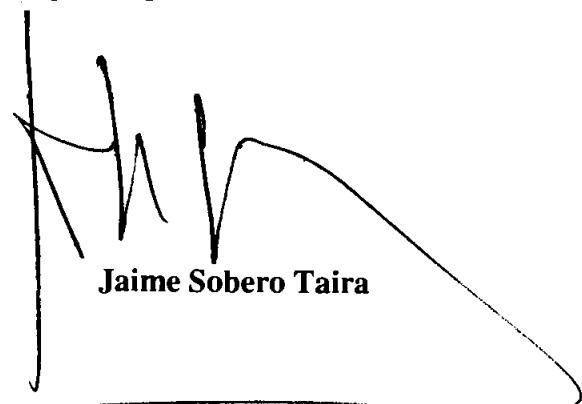

Este magnífico libro, que es el 4º volumen publicado por PROCOPA y que contiene 11 contribuciones de PROCOPA, representa un adecuado broche final del proyecto más productivo que IMARPE ha llevado a cabo en los últimos años.

Este libro, al mismo tiempo, inicia una nueva fase para nuestras investigaciones. Sobre la base de los datos y análisis que este contiene, así como aquellos incluidos en su volumen compañero publicado en 1987, harán posible finalmente, desarrollar el modelo de simulación orientado al manejo de los recursos pesqueros del sistema peruano de afloramiento.

El International Center for Living Aquatic Resources Management (ICLARM), con ayuda de GTZ, nos apoyarán en esta tarea.

A juzgar por el alto nivel alcanzado en la producción de este libro y el de su predecesor, y por la oportunidad en que se presentan, confiamos que este plan que producirá un modelo de simulación para el manejo de nuestra pesquería pelágica será exitosamente implementado y esperamos con gran interés su culminación.

Deseo tomar esta oportunidad para expresar a nombre de IMARPE, nuestro agradecimiento a GTZ e ICLARM por el esfuerzo puesto de manifiesto en este libro; particularmente al Dr. Salzwedel, penúltimo jefe de PROCOPA, por su apoyo al taller de trabajo que condujo a la publicación de este libro; al Dr. P. Muck, último jefe de PROCOPA, por nuestra fructífera cooperación; a Jaime Mendo e Isabel Tsukayama, por su aporte científico y editorial; a los participantes y observadores del taller de trabajo antes mencionado y habilmente presidido por J. Csirke de FAO. Deseo agradecer también a los Drs. M. Bilio y W. Schmidt de la sede central de GTZ por su incansable apoyo a PROCOPA, al US National Marine Fisheries Service por las contribuciones de varios de sus científicos, y por último en orden pero no en importancia, nuestro profundo agradecimiento al Dr. D. Pauly, por concebir el taller de trabajo que generó este libro y por el impulso brindado a todo el equipo comprometido hasta finalizar con las más de 400 páginas de esta obra.

GTZ Foreword

The pace of progress towards a comprehensive understanding of the Peruvian upwelling ecosystem is astounding: after only a decade of intensive research efforts, a fourth book on the subject can be published in the context of Peruvian-German cooperation in fisheries research.

The former books were:

- i. "El Niño, Su Impacto en la Fauna Marina", edited by W. Arntz, A. Landa and J. Tarazona (Bol. Inst. Mar Perú - Callao, Vol. extraord. 1985);
- ii. "The Peruvian Anchoveta and its Upwelling Ecosystem: Three Decades of Change", edited by D. Pauly and I. Tsukayama (ICLARM Studies and Reviews 15, 1987);
- iii. "Recursos y Dinámica del Ecosistema de Afloramiento Peruano", edited by H. Salzwedel and A. Landa (Bol. Inst. Mar Perú - Callao, Vol. extraord. 1988).

The present volume is another example of the catalyzing effect of ICLARM on international research cooperation, proving the effectiveness of a determined and methodologically well-organized approach to a clearly defined goal.

The four volumes, as the more bulky parts of a total of over 90 scientific contributions, are the most conspicuous evidence of the large written output produced by the Programa Cooperativo Peruano-Aleman de Investigación Pesquera (PROCOPA), funded by the German Ministry for Economic Cooperation (BMZ) and executed jointly by the Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ) GmbH and the Instituto del Mar del Perú (IMARPE). It is hoped that the wealth of information contained in these publications will be recognized and used by the competent authorities for the purpose for which it was produced: to serve as an indispensable management basis for a rational and sustained exploitation of the unique fishery resources of the sea off Peru.

Scientific progress of today is pushed ahead by an ever increasing potential of information analysis and interpretation through electronic data elaboration. Contrary to a former tendency to publish only secondary (or elaborated) data, it appears now more useful to make the entire sets of original data available to the scientific public in order to allow for future possibilities of even more sophisticated or otherwise differently-oriented analysis. Many tables of the present volume attest to the application of this principle, as was already the case in the second book of the above list.

The compilation of the present volume is considered the last step before the development of a simulation model for the management of the fishery resources of the Peruvian upwelling system. To develop such a model, all relevant biological, ecological, fishery and economic information will be integrated into one model, which will be parameterized using data sets now available as well as data that will emerge in the near future. With the help of this system, it should be possible to appraise at any time the advantages and disadvantages of different management options, taking into consideration the current size and fishery potential of the stocks, the ecological situation (and expected changes) in the distribution area, the requirements of economical fishing-fleet management, the fish prices on domestic and international markets and other relevant parameters. The task of making this concluding step has been entrusted to IMARPE and ICLARM staff.

In the Peruvian-German cooperation in fisheries research, a considerable number of internationally renowned scientists from countries other than Peru and the Federal Republic of Germany have been involved. Substantial amounts of original data have been contributed by researchers of the USA (see Pauly and Tsukayama 1987). In view of the extensive activities of Soviet research vessels off the Peruvian coast, it would be of great importance to have public access to pertinent data collected in research efforts made by the Soviet Union. This could probably contribute to an even broader and more complete view of the ecosystem, in particular by inclusion of additional information on the straddling stocks of mackerel and horse mackerel living within and outside of the Exclusive Economic Zone (EEZ) and affecting the anchoveta stocks as well.

I conclude by thanking those at IMARPE, PROCOPA and ICLARM who organized and ran the August 1987 workshop on "Models for Yield Prediction in the Peruvian Ecosystem" which led to this book, as well as the editors of this magnificent volume.

Martin Bilio

ICLARM Foreword

This book is the second volume produced by ICLARM dealing exclusively with Latin American resources. Like its predecessor, ("The Peruvian Anchoveta and its Upwelling Ecosystem: Three Decades of Change", edited by D. Pauly and I. Tsukayama, ICLARM Studies and Reviews 15, 1987), this book presents studies based on long time series which are fully documented in the form of tables included in each contribution. This volume goes beyond its predecessor, however, in that all of its figures and tables have English and Spanish legends. Also, the report of the workshop upon which this book is based, is presented in Spanish (see Csirke et al., this vol.). We hope this will make this book more accessible than its predecessor to our colleagues in Latin America and, in particular, Peru.

In addition, the editors have included as Appendix I of this book a brief documentation of twelve 5-1/4" diskettes for MSDOS (i.e., IBM PC compatible) microcomputers, available to outside researchers for a modest fee from ICLARM, and which contain all data used by the authors of contributions included in this volume and its predecessor. The editors hope, as do we at ICLARM, that this will encourage researchers in Peru and elsewhere to perform further and deeper analyses of these data; such analyses will benefit them as much as it will benefit, in the long term, the management of the Peruvian fisheries.

ICLARM is extremely pleased to have been able to contribute to the considerable efforts which went into the production of this volume. Particularly, I would like to express our thanks to Mr. Jaime Sobero Taira, Executive Director of IMARPE, and his predecessor, Mr. Rogelio Villanueva, for their support of the August 1987 workshop which led to this volume, and of the subsequent activities of this project; to Mr. Jaime Mendo and Ms. Isabel Tsukayama for their scientific and editorial inputs; to the Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ), particularly Drs. H. Salzwedel, P. Muck, M. Bilio and W. Schmidt; as well as to Drs. A. Bakun, R. Mendelssohn and R. Parrish of the US National Marine Fisheries Service for their willingness to contribute to this effort.

We at ICLARM look forward very much to our future cooperation with IMARPE and GTZ and hope that readers will find the present volume to be a useful contribution to the literature on Latin American resources.

Abstract

A summary and the conclusions of a workshop on "Models for Yield Prediction in the Peruvian Ecosystem", held on 24-28 August 1987 at the Instituto del Mar del Perú are presented. Emphasis is given to those presentations and discussions which pertained to long time series and to consistent data collection and to the key elements of a future model of the Peruvian upwelling ecosystem for use in fishery management.

Resumen

Se presenta un resumen y las conclusiones del "Taller de trabajo sobre modelos para la predicción del rendimiento en el sistema de afloramiento peruano", realizado el 24-28 de Agosto de 1987 en el Instituto del Mar del Perú. Se pone énfasis en aquellas presentaciones y discusiones referentes a series de tiempo de largo plazo, recolección de datos y a los elementos claves para un modelo futuro del ecosistema de afloramiento peruano para ser usado en el manejo pesquero.

*PROCPA Contribution No. 86.

** Present address: Monterey Bay Aquarium Research Institute, P.O. Box 20, Pacific Grove, California 93950, USA.

Introducción

La reciente publicación del libro "The Peruvian anchoveta and its upwelling ecosystem: three decades of change" (Pauly y Tsukayama 1987) pone a disposición de la comunidad científica internacional un gran volumen de información a nivel mensual desde 1953 hasta 1982 sobre la población y pesquería de la anchoveta peruana y de las condiciones del ambiente marino frente al Perú. Se incluyen además, algunos análisis preliminares y otros más detallados de los datos presentados en el libro.

Como una primera acción de seguimiento del valioso esfuerzo que significó reunir en un solo volumen datos de 30 años de investigaciones, PROCOPA, ICLARM e IMARPE decidieron convocar este taller de trabajo sobre "Modelos para la predicción del rendimiento en el sistema de afloramiento peruano" para lo cual se invitó tanto a los autores que habían contribuido con el libro, así como a otros expertos internacionales con el fin de discutir, ampliar y analizar la base de datos disponibles a la fecha.

Los objetivos del taller de trabajo fueron:

- i) revisar la base de datos disponible sobre el sistema de afloramiento peruano y discutir su utilidad para los fines de investigación y ordenamiento pesquero;
- ii) identificar modelos predictivos y métodos de ordenación que, teniendo en cuenta las características especiales del ecosistema del afloramiento peruano, puedan ser más adecuados que aquellos modelos de rendimiento en uso, donde por lo general se asume que el sistema está compuesto por stocks o unidades poblacionales aisladas que podrían ser mantenidos en un estado de equilibrio;
- iii) sugerir líneas de investigación de mayor interés, tanto para el personal del IMARPE, como el personal de PROCOPA y otros grupos o agencias de asistencia bilateral o internacional vinculadas al sector pesquero peruano, así como a la comunidad científica internacional.

El taller de trabajo se llevó a cabo en el Instituto del Mar, Chucuito, Callao, Perú, del 24 al 28 de Agosto de 1987 y contó con la participación de científicos de IMARPE, PROCOPA e ICLARM como organismos auspiciadores, así como de otros organismos nacionales e internacionales. La lista de participantes se presenta en Tabla 1. El taller se inició el día lunes 24 de Agosto de 1987 con las palabras del Blgo. R. Villanueva, Director Ejecutivo del IMARPE, a cuya sugerencia se rindió homenaje a la fallecida Dra. H. Santander, guardando un minuto de silencio. Sigueron las palabras del Dr. H. Salzwedel, en representación de PROCOPA y del Dr. D. Pauly, en representación de ICLARM. El Almirante AP (R) R. Zevallos Newton, Presidente del Directorio del IMARPE, dió por inaugurado el taller de trabajo.

Por aclamación se eligió al Blgo. J. Csirke, de la FAO, como Presidente del Taller de Trabajo y al Blgo. J. Mendo, del IMARPE como Relator, luego de lo cual se procedió con las sesiones del Taller según la agenda aprobada.

Las sesiones consistieron de dos fases. Los dos primeros días se efectuaron las presentaciones y discusiones de trabajos de investigación y datos originales que amplían, complementan o analizan los datos y resultados ya publicados en el libro, luego de lo cual se procedió a formar dos grupos de trabajo con la finalidad de puntualizar dos de los aspectos generales de mayor importancia para el Taller:

- a) El muestreo, colección y análisis de datos, que fue asignado al grupo que se reunió bajo la coordinación del Ing. J. Zuzunaga de IMARPE, actuando como relatora la Blga. G. Cárdenas, y
- b) Desarrollo de modelos, asignado al grupo que se reunió bajo la coordinación del Dr. P. Muck de PROCOPA y donde actuó como Relator el Dr. F. Chávez, del Duke University.

Luego de haber sido discutidas en plenario, las contribuciones de estos dos grupos de trabajo fueron incorporadas como partes principales del presente Informe.

Trabajos Presentados

Dentro de las primeras actividades del Taller de Trabajo se programó la presentación y discusión de resultados preliminares y avances de trabajo donde se hubieran utilizado los datos

publicados en el libro editado por Pauly y Tsukayama (1987), así como la presentación de nuevos datos que podrían ser considerados en las series de tiempo disponible.

La primera presentación estuvo a cargo del Dr. Max Agüero (ICLARM), quien sustentó su trabajo anterior (Agüero 1987) y en el que se trata de integrar en un modelo de programación matemática, los diferentes componentes del sector pesquero con el objeto de determinar el rendimiento económico óptimo en la explotación de un recurso (por ejemplo la anchoveta).

Dicha presentación hace una revisión de la evolución de la pesquería de la anchoveta desde el punto de vista económico, basado en los datos del libro antes mencionado.

La versatilidad del modelo está dada por la inclusión de diferentes curvas de rendimiento, datos ambientales, variación de precios, esfuerzo de pesca, etc.

En base a lo presentado por el Dr. Agüero, se llegó a la conclusión de que si se tiene como objetivo maximizar el rendimiento económico neto de la pesquería, será necesario ajustar modelos como el propuesto donde se integra la parte biológica y los aspectos económicos. Esto daría lugar a un trabajo conjunto entre las entidades que se dedican a la investigación (i.e., IMARPE) y a las que planifican la economía en el sector pesquero (Instituto Nacional de Planificación, Ministerio de Economía y Finanzas, etc.).

La experiencia del colapso de la anchoveta en los años setenta y la necesidad de evitar que se repitan, nos obliga a ésta integración, ya que por un lado se estará preservando el recurso y por otro, se obtendrá un rendimiento económico superior.

La presentación del Dr. M. Bohle-Carbonell sobre cambios temporales del sistema de afloramiento peruano, analizando los datos de series de tiempo disponible, llega a la conclusión que muchos rangos de variables independientes están describiendo un camino fraccional al azar (Bohle-Carbonell, este vol.).

Los análisis espectrales de las series de tiempo muestran una variabilidad temporal de mucho ruido ("noisy temporal changes") con una señal estacional débil ("weak seasonal signal").

Así mismo, para rangos cubiertos por la variable independiente no se ha encontrado un ajuste, por lo que los cambios de las variables dependientes son más complicados que lo asumido por un modelo estadístico simple.

La interpretación geométrica indica que dentro de los datos observados existen rangos de combinaciones de parámetros improbables. Ciertos valores o combinaciones de valores de la variable dependiente no son posibles de obtener. Desde el punto de vista biológico esto puede significar que el sistema se encuentra en múltiples estados de equilibrio.

Esta presentación sugiere que el modelaje y el análisis de datos debe tratarse con un sentido estadístico.

El Dr. F. Chávez (Duke University, Marine Lab.) contribuyó con la presentación de un modelo para estimar el potencial de la nueva producción primaria, usando series de tiempo mensuales de 1953 a 1984. El se basó en datos de afloramiento y profundidad de la termoclina publicados por Bakun (1987) y Brainard y McLain (1987), respectivamente. La profundidad de la termoclina fue convertida a concentración de nitrógeno a los 60 m usando una relación entre la profundidad de la termoclina y la concentración de nitrato a 60 m.

Durante los años de "El Niño" aumenta el transporte vertical (afloramiento), pero la concentración de nutrientes en las aguas afloradas son bajas. Este incremento en el transporte vertical hace que la producción primaria estimada por el modelo durante los años "El Niño" sea más alta de la esperada (Chávez et al., este vol.).

Este modelo simple puede ser muy útil para el cálculo de los nutrientes en base a parámetros físicos, sin embargo la parametrización de las variables debe mejorarse con el objeto de que el modelo adquiera una mayor robustez (ver Mendo et al., este vol.).

Un resumen del estado actual de la investigación cuantitativa del macrobentos en el Perú fue presentado por el Dr. Horst Salzwedel (PROCOPA). La mayoría de los trabajos cuantitativos se publicaron después de 1980, siendo las áreas de mayor interés la Bahía de Ancón (40 km al norte de Lima) y la plataforma continental entre 12°S (Callao) y 30°S (Ecuador). Para la Bahía de Ancón, existen series de tiempo de datos desde 1981 hasta la fecha, cubriendo así años normales y años "Niño". Para el sublitoral, más allá de los 25 m de profundidad hay sólo tres cruceros efectuados por el IMARPE (1981, 1983 y 1984) de los cuales el material ha sido evaluado hasta el nivel de especies.

Una recopilación de los datos existentes revela los siguientes resultados: Niños moderados (1976, 1987) suben la concentración promedio del oxígeno y la temperatura de las aguas cercanas al fondo sólo hasta los 9°S aproximadamente. Se encuentran con altas biomassas y densidades y bajo número de especies, siendo ellas bien adaptadas a las bajas concentraciones de oxígeno durante años normales. Uniendo los datos del sublitoral de 3 m hasta 4,000 m de profundidad resaltan desfases en las biomassas y las densidades en aproximadamente 80 m de profundidad que por ahora no se han podido explicar por la cantidad limitada de datos evaluados.

Se concluye que los conocimientos cuantitativos del macrozoobentos son muy escasos para poderlos relacionar en forma adecuada con las largas series de tiempo que existen para otros

datos abióticos y bióticos contenidos en el libro. Se recomienda continuar con las investigaciones regulares en la Bahía de Ancón y ampliarlas a aguas más profundas.

La Dra. P. Majluf (Cambridge University), presentó algunos aspectos de la ecología y producción del lobo fino (*Arctocephalus australis*) de Punta San Juan, Perú ($15^{\circ}22'S$) durante 1983 y 1987, así como de la dieta, comportamiento alimenticio, reproducción, crecimiento y mortalidad de crías. Los resultados indican que los lobos consumen predominantemente anchoveta adulta y que las variaciones en la disponibilidad local para la flota pesquera se reflejan en la composición y diversidad de la dieta.

Con referencia a otras especies de lobos del mismo género, las mortalidades encontradas fueron altas, especialmente durante el fenómeno de "El Niño" 1982-83 y en 1984-85. Las mayores mortalidades de las crías (de 0-30 días de edad) durante la temporada de reproducción (40%), se debió principalmente a la alta densidad de hembras en la playa donde se reproducen. La mortalidad entre los 30 días y un año de edad parece estar relacionada con cambios en la disponibilidad de anchoveta adulta para los lobos (Majluf, este vol.).

El incremento de la población de lobos coincide con un incremento en su protección; sin embargo no se descarta el efecto de la disponibilidad local del recurso de anchoveta principalmente para las madres.

El análisis presentado por la Sra. Majluf, sugiere que se podría tomar a los lobos como un indicador de la disponibilidad local de anchoveta y por lo tanto, como una medida de la captura por unidad de esfuerzo.

Por otro lado, dado el daño que provoca la población de lobos a los pescadores locales, es importante plantear la alternativa de utilizar a los lobos como un atractivo turístico. Esto permitiría el ingreso de divisas que compensarían las pérdidas de los pescadores en cuanto a redes se refiere.

El Blgo. A. Alamo (IMARPE), expuso un análisis preliminar del contenido estomacal de la anchoveta. En su presentación hizo la comparación de la dieta de la anchoveta bajo los efectos de "El Niño" y bajo condiciones normales. Durante "El Niño" se incrementó la proporción de copépodos consumidos por anchoveta. Para la interpretación de estos cambios, se sugirió que se realice un análisis multivariado tomando en cuenta variables tales como temperatura, hora, día, estacionalidad, variaciones interanuales, latitud, etc. Este estudio se podrá llevar a cabo en el futuro utilizando la base de datos disponibles sobre contenido estomacal (ver Rojas de Mendiola, este vol., Alamo, este vol., Pauly et al, este vol.).

El Blgo. H. Tovar (IMARPE) presentó los resultados de un estudio sobre la predación del piquero (*Sula variegata*, Tschudi) sobre algunos recursos ícticos del litoral peruano, sosteniendo que en febrero de 1986, el piquero se alimentó principalmente de anchoveta (*Engraulis ringens* J.) y en menor proporción de otras especies como sardina (*Sardinops sagax*), jurel (*Trachurus murphyi*), pejerrey (*Odonthestes regia*), cojinova (*Seriola violacea*), anchoveta blanca (*Anchoa nasus*) y de agujilla (*Scomber saurus*). Dentro de la discusión de éste tópico se consideró de interés el uso de los bolos alimenticios como un indicador local de la población de anchoveta y de su disponibilidad como alimento. Por otro lado, se enfatizó la necesidad de continuar con la obtención de información mensual de las poblaciones de aves guaneras, así como la realización de censos poblacionales para lo cual es necesario la coordinación con la Dirección de Fertilizantes de Pesca-Perú.

El Dr. P. Muck (PROCOPA), presentó una revisión general de las tendencias mostradas por las poblaciones incluidas en el libro de Pauly y Tsukayama (1987). En su análisis, mostró que las poblaciones de anchoveta, bonito y aves guaneras disminuyeron entre los años 1960 y 1980, y la flota bolichera a partir de 1970. Sin embargo la disminución de la flota no fue suficiente para evitar la drástica disminución de dichas poblaciones. La merluza (*Merluccius gayi*), jurel y caballa se mantuvieron estables y la sardina y los lobos marinos aumentaron su población durante el período cubierto por el estudio.

Se señaló que la sobrepesca fue la principal responsable del descenso de las poblaciones mencionadas en primer término. Por otro lado el jurel, merluza y caballa incrementaron sus poblaciones ya que sufrieron capturas limitadas y no son dependientes de la disponibilidad de anchoveta. El incremento del stock de sardina en cambio está asociado a la disminución del stock de anchoveta, la que preda los huevos de sardina y además compite con ella por el

alimento. Por otro lado, el incremento de la población de lobos marinos se debió principalmente al incremento de la protección legal.

En general, los cambios biológicos observados en el ecosistema peruano en los 20 años, se deben principalmente a los efectos directos e indirectos de la sobre pesca y al fenómeno de "El Niño" que actuó solo como un factor agravante (Muck, este vol.).

La Blga. S. Carrasco (IMARPE), presentó las variaciones de la biomasa del zooplancton en el mar peruano en base a muestreos realizados por IMARPE durante el período 1964-1987. Los resultados indicaron una disminución notable de los valores de biomasa a través de los años (ver Carrasco y Lozano, este vol.). Se observa una similitud entre las variaciones en la biomasa de zooplancton y la variación en la biomasa de anchoveta, sugiriendo que en la década de los años 60 existía un ecosistema (no sólo en lo que se refiere a peces pelágicos) diferente al que existe actualmente. Igualmente durante los años "El Niño" existen cambios en la distribución de zooplancton, en los que se observa que los máximos en la abundancia se encuentran más alejados de la costa que en condiciones normales y así mismo, una disminución en la abundancia de zooplancton. Se concluye al respecto la necesidad de estudiar las causas de ese decrecimiento en relación con el fitoplancton, el consumo de peces planctívoros, etc. Se hizo hincapié que aún existen muchos datos históricos que necesitan trabajarse. Se recomienda que esta información sea extraída, estandarizada y publicada.

El Blgo. J. Csirke (FAO), presentó un análisis de las fluctuaciones del coeficiente de capturabilidad mensual para el período comprendido entre el año 1961 y el año 1972, el cual será ampliado con nuevos datos disponibles en IMARPE para los años más recientes (ver Csirke, este vol.). Los resultados presentados muestran una clara estacionalidad en la fluctuación del coeficiente de capturabilidad, el que alcanza valores máximos en los meses de verano y disminuye considerablemente en invierno. El resultado más interesante es que los datos muestran una relación inversa entre el coeficiente de capturabilidad y la biomasa de anchoveta, donde el coeficiente de capturabilidad aumenta en forma exponencial a medida que la biomasa total disminuye. Este tipo de relación es semejante al encontrado en algunas poblaciones de peces pelágicos pequeños en otras partes del mundo, y constituye una primera prueba de que en la anchoveta peruana también se da este tipo de relación depensatoria que implica un aumento de la mortalidad por pesca a menor abundancia del recurso. Este hallazgo también refuerza la observación hecha a inicios de los años setenta de que la capturabilidad de la anchoveta no era constante, en base a lo cual se abandonó la colección y uso de datos de captura por unidad de esfuerzo para estimar fluctuaciones del recurso y para la aplicación de modelos de producción. Los resultados presentados demuestran sin embargo que, al ser posible determinar la posible relación entre el coeficiente de capturabilidad y la biomasa total, es posible usar esta información para corregir los valores de captura y esfuerzo. Se recomendó por tanto que se reinicie e intensifique la colección de datos de esfuerzo usando en lo posible medidas alternativas del poder de pesca, los cuales constituyen un medio útil para monitorear las fluctuaciones de la abundancia a bajo costo, los cuales sin embargo, se deberán validar y complementar con estimaciones hechas por otros métodos.

El Dr. P. Lagos (IGP) presentó un trabajo sobre la variabilidad estacional de la temperatura superficial a lo largo de la costa del Perú. Usando las series de tiempo mensuales de calor neto local, transporte Ekman y profundidad de la isoterma de 14°C, se ha llegado a pronosticar la estacionalidad media de la temperatura superficial del mar.

El concluye que la estacionalidad media consiste de una variabilidad anual debida al calor local, probablemente con un cambio pequeño de la amplitud y fase de año a año y de una variabilidad semi-anual debido a la dinámica interna del océano.

Los resultados del estudio de balance del calor pueden ser usados en el desarrollo de los modelos físico-biológicos que requieren las tendencias de las condiciones ambientales.

Modelaje del Ecosistema Peruano

Necesidad de un Modelo

En la actualidad los administradores de la pesca no disponen de un instrumento para predecir las fluctuaciones anuales de la biomasa de recursos pesqueros. La pesquería pelágica

frente a Perú está compuesta de múltiples especies, cuya abundancia relativa es una función de la pesquería y de los cambios bióticos y abióticos. Para tratar con un gran número de propiedades que varían con el tiempo y que afectan en forma diferenciada la abundancia de cada especie, es necesario algún tipo de modelo computarizado capaz de simular el ecosistema pelágico. Este modelo ayudará a estimar el esfuerzo con que deberá explotarse cada una de las especies que componen el ecosistema. Por ejemplo, el modelo podrá mostrar como la biomasa de la especie A podría afectar la biomasa de la especie B (para la costa peruana las especies A y B podrían ser anchoveta y sardina). El modelo podría tener no sólo valor predictivo sino también de diagnóstico, por lo que podría utilizarse también para explorar posibles interacciones. En este nivel, el modelo identificaría los componentes críticos del ecosistema (y sus funciones que la deciden) lo cual requiere estudios más detallados. En el futuro, éste modelo también proveería los datos requeridos en un modelo económico.

Tipo de Modelo Necesario

Este tópico requiere de un amplio estudio. Se sugiere varios niveles o tipos de modelo que pueden intentarse:

- a) Un modelo de "anchoveta" que utilice la serie de tiempo disponible para predecir el reclutamiento en base a las relaciones con los factores bióticos y abióticos para el manejo de los recursos.
- b) Un modelo de evaluación de stock de peces que incluya sólo aquellos elementos de magnitud suficiente como para alterar los stocks de peces. Por ejemplo, los mamíferos que no predan peces a altos niveles deberán ser excluidos.
- c) Un modelo del ecosistema que adicione al modelo de evaluación del stock de peces aquellos elementos del sistema pelágico que no fueron incluidos en el ejercicio previo. Estos elementos (por ej. aves y mamíferos) no afectan la variabilidad de los stocks de peces, sin embargo, son afectados por la variabilidad en los stocks de peces. Estos elementos tienen valor socio-económico y requieren ser tomados en consideración.

El desarrollo del modelo deberá considerar siempre el gran objetivo, cual es definir el nivel de explotación de un stock y la especie preferida.

Validez del Modelo

El modelo contemplará, en base a la serie de tiempo disponible, (1) la entrada de datos para el modelo, y (2) la verificación de la validez del modelo. Un modelo predictivo y realístico deberá captar la estructura esencial de la serie de tiempo existente.

A continuación se presenta el concepto iterativo simple del desarrollo del modelo:

- a) empezar con el modelo conceptual más simple,
- b) desarrollar funciones de transferencia,
- c) correr el modelo utilizando datos mensuales y comparar los datos observados, y
- d) mantener o cambiar las funciones de transferencia para obtener un "mejor" dato simulado.

Forma Conceptual del Modelo

El modelo conceptual deberá incluir: 1) producción primaria y secundaria, los peces (anchoveta, sardina, jurel, caballa y merluza) y la pesquería como parte del componente biótico; y 2) temperatura superficial del mar, fuerzas metereológicas locales y remotas y temperatura subsuperficial como parte del componente abiótico. El modelo de ecosistema incluirá aves y mamíferos (ver Fig. 1).

Las dos dimensiones predictivas importantes del modelo son el espacio y el tiempo, requiriéndose también la componente geográfica. La resolución espacial deberá incluir el área

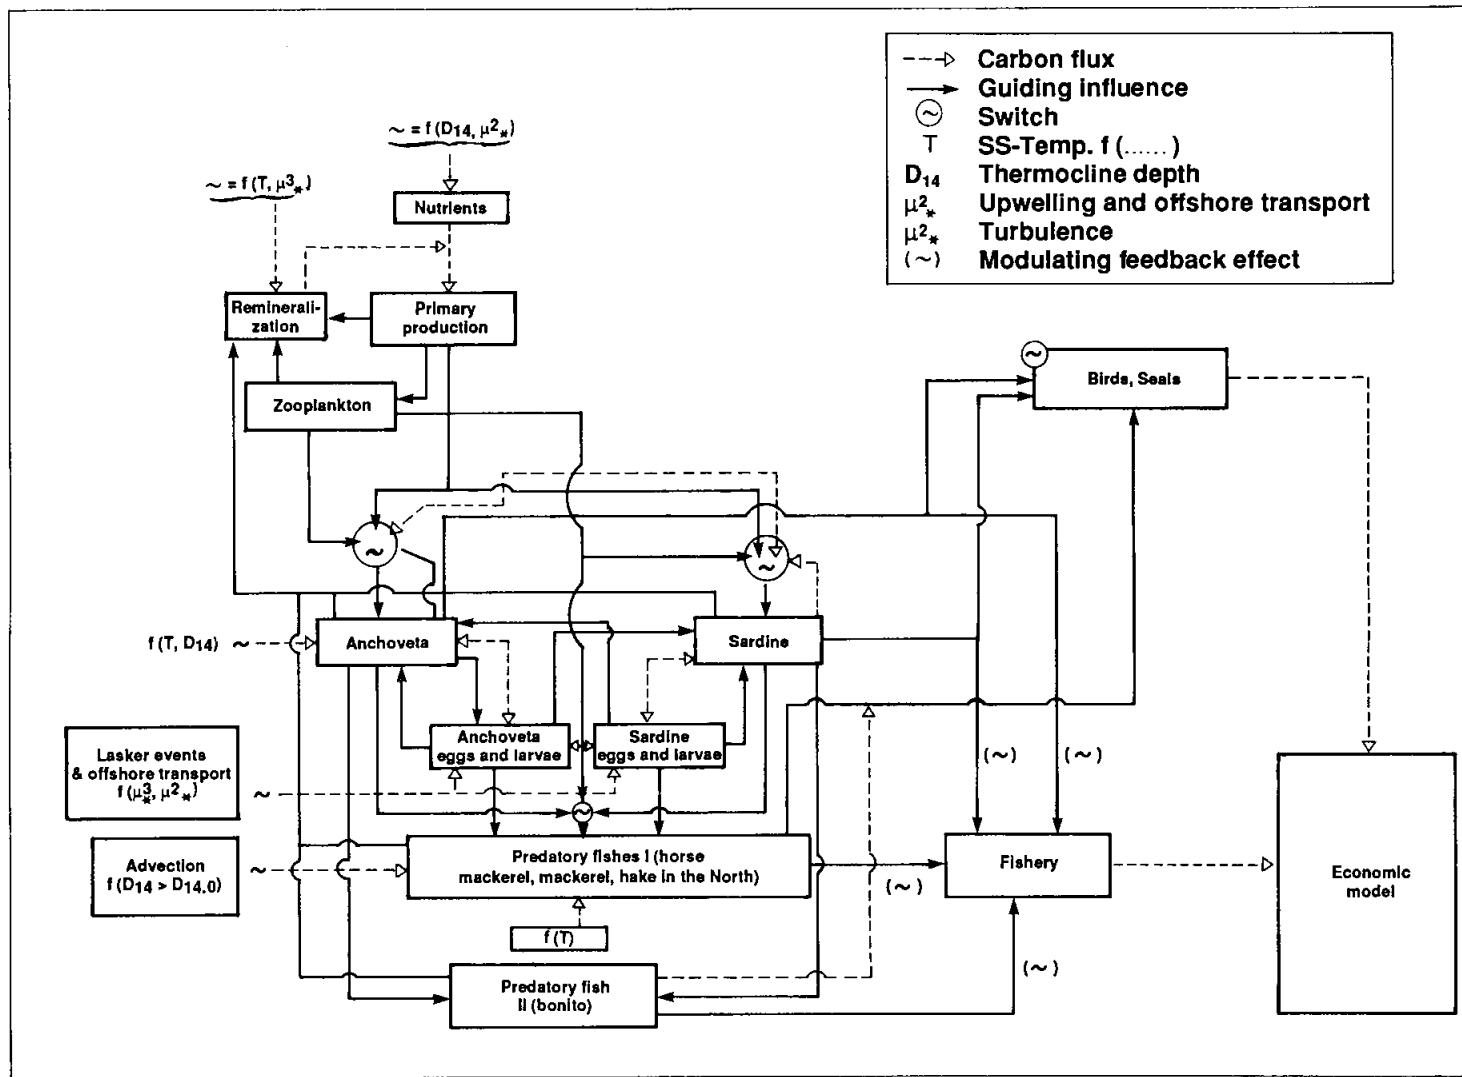

Fig. 1. Elementos a ser considerados en un modelo de simulación del ecosistema de afloramiento peruano. Notar el papel importante de la temperatura superficial del mar (TSM) y los parámetros derivados del viento.

Fig. 1. Elements to be considered in a simulation model of the Peruvian upwelling ecosystem. Note strong role of SST- and wind-derived parameters.

principal de distribución de la anchoveta, esto es 4-14°S y 60 millas mar afuera, que de ser necesario podría ser dividida.

Los Datos y sus Características

La serie de tiempo existente, gran parte de la cual ha sido compilada y publicada en Pauly y Tsukayama (1987) provee una base de datos suficiente para iniciar el modelaje de multiespecies. Las series de tiempo de datos que aún faltan (por ej. zooplancton) deberán reconstruirse utilizando la literatura y datos no publicados de IMARPE y/o por funciones de transferencia a partir de por ej., la producción primaria.

El modelo deberá simular los cambios de los peces en cada paso. Ello significa que el modelo deberá incluir efectos no lineales. Existen modelos que ya simulan pasos como cambios en las poblaciones de peces, pudiendo incorporarse dichas ecuaciones en el presente modelo.

Los diferentes compartimentos del modelo deberán mantener un grado similar de complejidad de forma que sean compatibles. Por ejemplo, el comportamiento de producción primaria deberá ser compatible con el de producción de peces.

La gran cantidad de características oceanográficas deberá ser investigada, poniendo particular atención en los cambios que pudieran no haber sido observados en las estaciones costeras. Un ejemplo es la distribución de las aguas sub-tropicales superficiales (ASS) que podrían definir el tamaño del habitat de la anchoveta. Existen evidencias de cambios sistemáticos en la distribución de estas masas de aguas con anterioridad a la generación de perturbaciones que se propagan hacia el Este (ondas Kelvin) en el Pacífico Oriental (Bohle-Carbonell, este vol.). La fuerza remota es responsable de los dramáticos efectos de "El Niño"; sin embargo, los cambios que ocurren antes del fenómeno de "El Niño" también pueden tener efectos dramáticos sobre las poblaciones de peces. Se recomienda mantener comunicación con modeladores que trabajan a mayor escala (por ejemplo con aquellos que trabajan con la zona del Pacífico Tropical de Australia a América del Sur).

Acciones Futuras

Deberá continuarse con el muestreo que provee los datos para la serie de tiempo existente. Estos incluirán datos de biomasa temporal y espacial, elementos biológicos del modelo, comportamiento de alimentación, tasas de explotación (captura), así como factores abióticos tales como viento y datos hidrográficos. Los datos deberán estandarizarse y analizarse en tiempo real a fin de proveer las entradas de datos requeridas en el modelo. Se pondrá especial atención a la colección de datos de composición, biomasa y producción del fitoplankton y zooplancton.

Para lograr el gran objetivo del modelaje, cual es el de crear un instrumento para el manejo pesquero, IMARPE y PROCOPA deberán formalizar un compromiso para este modelaje mediante la conformación de un grupo de trabajo.

Los esfuerzos para el modelaje deberán iniciarse lo antes posible. La información compilada y publicada en Pauly y Tsukayama (1987), en este volumen, así como los datos de IMARPE aún no procesados, son suficientes para iniciar el modelaje del ecosistema del mar peruano.

Análisis y Colección de Datos

Las diferentes actividades que deben desarrollarse en el análisis y colección de datos han sido divididas de acuerdo a la necesidad de implementar nuevos datos de series de tiempo, al procesamiento de éstos y a las prioridades que se deberán tener en cuenta para el modelaje del ecosistema. Estas se resumen de la siguiente forma:

A. Colección de Datos

Dentro de la gama de información factible de ser colectada se ha priorizado aquellas indicadas en la Tabla 2 adjunta.

Tabla 2. Colección de datos generales para los estudios de investigación de IMARPE.

| TIPO | FUENTE | INFORMACION ESPECIFICA | FRECUENCIA | |
|-------------------------|-------------------------------------|----------------------------|---------------|--------------------|

B. Evaluación de las prioridades y problemática

Los datos colectados por IMARPE deben estar orientados al logro de dos aspectos fundamentales:

- Optimizar el asesoramiento al gobierno, particularmente al sector pesquero en la toma de decisiones para un mejor manejo de los recursos.
- Desarrollar modelos propios del ecosistema aplicando metodologías que tengan capacidad predictiva.

Para el logro de estos objetivos se señala la necesidad de resolver problemas referentes a:

- Alto costo que requiere la toma de información a través de las exploraciones en el mar, muestreo de pesquerías, adquisición y mantenimiento de equipos de laboratorio, transporte, etc.
- Insuficiencia de recursos humanos y necesidad de capacitación permanente del personal existente que se encarga de la colección de datos.
- Deficiencia de coordinación y apoyo de entidades estatales y privadas del sector pesquero e instituciones afines.

C. Análisis de la Información

La información colectada deberá ser procesada y analizada utilizando los métodos disponibles, enfatizándose la necesidad de estandarización de los mismos y el uso máximo de las computadoras disponibles en el IMARPE. El objetivo final deberá ser la publicación de los resultados.

D. Política de intercambio de datos

El intercambio de datos se plantea en dos niveles:

- Difusión inmediata de datos, sujeto simplemente a la culminación de su recopilación, consistencia y procesamiento básico.
- Difusión mediata, con la elaboración de informes científicos e informes varios.

La oportuna difusión de la información en ambos niveles estará condicionada por las facilidades de edición y publicación de informes.

Conclusiones y Recomendaciones

En base a las presentaciones que se hicieron durante los dos primeros días del taller y las discusiones sostenidas en Plenario y en los Grupos de trabajo, se llegó a las conclusiones y recomendaciones siguientes:

- a) El conocimiento científico acumulado hasta la fecha debe volcarse en un modelo que permita predecir las fluctuaciones anuales de la biomasa de recursos pesqueros, además de poder ser utilizado para explorar los resultados de distintas alternativas de administración o manejo pesquero.
- b) Además del modelo del ecosistema del mar peruano se requiere un modelo que integre tanto la parte biológica, como los aspectos económicos. Este tipo de modelo será particularmente útil si se tiene como objetivo maximizar el rendimiento económico neto de las pesquerías peruanas y requerirá un trabajo y colaboración más estrecha entre las entidades nacionales que se dedican a la investigación (IMARPE) y los que planifican la economía en el sector pesquero (Ministerio de Pesquería, Instituto Nacional de Planificación, Ministerio de Economía y Finanzas).
- c) Los esfuerzos para concretar la formulación de estos modelos deben iniciarse lo antes posible, considerándose que la información publicada en el libro editado por D. Pauly e I. Tsukayama recientemente, la información incluida en éste volumen y los datos aún no procesados que posee IMARPE son suficientes para iniciar el modelaje del ecosistema del mar peruano.
- d) Para permitir que este modelo pueda ser empleado en forma efectiva en el futuro, se recomienda que se continúen los muestreos que proveen de datos para actualizar las series de tiempo disponibles. Esto incluye datos sobre cambios de la biomasa y las capturas, así como otros elementos biológicos (alimentación, plancton, etc.) y factores abióticos (vientos, datos hidrográficos, etc.).
- e) Para lograr este gran objetivo de modelar el ecosistema del mar peruano, el IMARPE deberá propiciar la formación de grupos de trabajo conformados por científicos altamente especializados del país y del extranjero, cuya participación en este ejercicio podrá ser canalizada en base a la cooperación técnica bilateral e internacional ya existentes u otros que podrían instituirse en el futuro. Dentro de este contexto, PROCOPA ha jugado un rol catalizador muy importante que, en opinión del Taller de trabajo, debería ser continuado y reforzado para apoyar al IMARPE en la puesta en práctica e implementación de las otras recomendaciones que se hacen en este Informe. Se consideró que también se debería estimular la participación de otras agencias y organismos de asistencia técnica internacional,

resaltándose el apoyo recibido de ICLARM, así como la participación de la FAO en este taller.

- f) Con respecto al colapso de importantes pesquerías y la disminución de algunos recursos del ecosistema del mar peruano tales como la anchoveta, el bonito y las aves guaneras, el taller concluyó que aún cuando los cambios del ambiente han jugado un rol importante, fue la sobrepesca la causa principal del colapso y disminución de estas poblaciones. Otras poblaciones como jurel, merluza y caballa han aumentado en los últimos años ya que han sido explotadas en forma limitada y no dependen de la disponibilidad de anchoveta. En cambio el aumento de la población de sardina sí parece estar asociado con la disminución de las poblaciones de anchoveta, a nivel de predación de huevos y competencia por alimento.
- g) En el taller se mostró que es posible encontrar una estrecha relación entre el coeficiente de capturabilidad y la biomasa total, lo cual permitiría corregir los datos de captura por unidad de esfuerzo cuyo uso para fines de evaluación de la pesca se abandonó a inicios de los años 70 al constatar que la capturabilidad no era constante. Dado que sería posible corregir y usar los valores de captura y esfuerzo, se recomienda que se reinicie y se refuerce la colección y procesamiento de este tipo de datos, los cuales constituyen un medio útil y de bajo costo para monitorear las fluctuaciones de la abundancia del recurso, complementando así las estimaciones que se hacen con otros métodos. Esta información de captura y esfuerzo podrá también ser empleada en análisis económicos de la pesca.
- h) El taller también acordó resaltar que hay información sobre la abundancia y comportamiento de aves y mamíferos marinos que pueden ser empleados como indicadores de posibles cambios en el ecosistema y en las poblaciones de peces. Se acordó por lo tanto recomendar que se continúe con la colección y el análisis de la información mensual de la población de las aves guaneras y que se prosiga con los censos poblacionales en coordinación con la Dirección de Fertilizantes de Pesca-Perú. Se recomienda así mismo que se considere también la posibilidad de emplear los bolos alimenticios de aves guaneras para obtener información sobre estructuras por tamaños y disponibilidad de anchoveta. Se señaló también que los lobos marinos podrían ser empleados como indicadores de la disponibilidad local de anchoveta.
- i) En cuanto a otros datos biológicos, se recomienda que se intensifiquen los estudios de alimentación de peces en sus diferentes estadios y, como parte del sistema de colección de información en el mar, se recomienda que se establezcan estaciones fijas para la colección de muestras y datos biológicos en forma similar a como viene haciéndolo el grupo de oceanografía del IMARPE para obtener datos abióticos.
- j) Para mejorar la colección y análisis de datos se recomendó que se realicen conversatorios periódicos para evaluar los sistemas de colección y procesamiento de datos.
- k) Se resaltó que uno de los objetivos finales y principales de todo trabajo científico es publicar los resultados de las investigaciones y se recomendó que los científicos del IMARPE tengan esto como meta final. Para ello se requerirá que al preparar proyectos de investigación se asegure la asignación de fondos necesarios para publicar los hallazgos del proyecto.

Abstract

The behavior of the Peruvian upwelling ecosystem is shown to be determined to a large degree by random events which make it oscillate between multiple disjoint states. The mean characteristics of these nonstationary random processes were identified partly as resulting from a correlated fractal noise process. Thus, any prediction of future changes of the Peruvian upwelling ecosystem must consider its stochastic nature. Predictions relevant for management decisions for periods longer than some months ahead may be beyond reach. However, physical parameters were identified which are most closely related to changes of anchoveta biomasses than those commonly observed to characterize El Niño events. This allows the development of new monitoring schemes and will lead to a better understanding of the dynamics of the interface between physics and biology in the Peruvian upwelling system.

Resumen

Se demuestra que el comportamiento del ecosistema peruano de afloramiento está determinado, en un alto grado, por eventos aleatorios que lo hacen oscilar entre múltiples estados disjuntos. La media característica de estos procesos aleatorios no estacionarios fué identificado parcialmente como un resultado de procesos correlacionados de ruido fractal. Es decir, una predicción de futuros cambios del ecosistema peruano de afloramiento debe considerar su naturaleza estocástica. Predicciones relevantes, para decisiones administrativas, de períodos mas allá de algunos meses están probablemente fuera de alcance. Sin embargo, fueron identificados parámetros físicos, los cuales están más cercanamente relacionados a cambios de la biomasa de anchoveta que aquellos comúnmente observados para caracterizar los eventos de El Niño. Esto permite el desarrollo de nuevos esquemas de monitoreo y conducirá a un mejor entendimiento de las dinámicas de la interfase entre física y biología en el sistema peruano de afloramiento.

Introduction

The Peruvian upwelling system is one of the most productive fishing grounds of the world. Its fishery yields depend in a complex manner, as recently illustrated in a monograph edited by Pauly and Tsukayama (1987), on physical and nonphysical conditions. However, a clear understanding of many of the underlying mechanisms is still lacking.

The question to be tackled here concerns the predictability of the Peruvian upwelling system. However, no prognostic will be given; rather, the past will be investigated to determine how much of the observed changes were due to random events. Thus, it is the degree of stochasticity of the Peruvian upwelling system which is dealt with here. Less stochasticity will be assumed to imply a high degree of predictability.

It may seem strange to attribute the label "stochastic" to an ecosystem, especially if, as generally, each individual interaction in this ecosystem can be described in a deterministic way. However a deterministic description of any system is no assurance against probabilistic properties of that same system (Lasota and Mackey 1985). The prerequisite of stochastic properties, or apparently chaotic behavior, is a nonlinear and dissipative dynamic system (Bohr

and Cvitanovic 1987). This prerequisite is fulfilled with regard to the nonlinearity of the physical laws of hydrodynamics and to most biological processes. The nondissipative character of the system will depend on a special choice of the dynamic constants.

The physics of the Peruvian upwelling system are locally and remotely forced by meteorological events. The local winds drive the upwelling and the remote winds over the central Pacific trigger perturbations which may reach the Peruvian coast. The fluctuations of the winds around the seasonal and diurnal average conditions are random. When the forcing is stochastic, e.g., a white noise, the response of the forced system may quite well be deterministic, if it is a well-tuned oscillator. But, does the Peruvian upwelling system function like a well-tuned oscillator?

The Peruvian upwelling system is sensitive to El Niño - Southern Oscillation (ENSO) events. These events are understood as produced by the feedback of the ocean atmosphere dynamics (Philander and Seigel 1985) leading first to a slow build-up of potential energy and second to its quick release. How the release is triggered is not well understood (Käse 1985) and even low-latitude volcanic eruptions cannot be disregarded as a triggering mechanism (Hofmann 1987). However, independently of the trigger, this auto-oscillation (D. Seidov, Acad. Sc., Moscow, USSR, pers. comm.) is only quasi-periodic and randomly forced sea surface temperature anomalies may be the crucial trigger mechanism (Ponte 1986). Thus, the timing and strength of El Niño events are probably random occurrences.

Going up the hierarchy, the biology of the Peruvian upwelling system is, as anywhere, a complex web of interactions between different species and the nonbiological environment. The interactions may be known or hypothesized to exist, but are generally not evaluated with regard to their relative importance. Thus, no theoretical estimate is available to evaluate if an ensemble of external perturbations of the ecosystem will propagate deterministically or diffuse randomly through it. Furthermore, no theoretical estimate can be derived to evaluate the influence of the stochasticity inherent to the physical environment on the biology.

Some interactions of the species in and with the Peruvian upwelling system are known, e.g., the cannibalization of anchoveta eggs by anchoveta (*Engraulis ringens*) (see Pauly and Soriano, this vol.). Historically, up to some months before the occurrence of the surface signal of the 1971-1972 El Niño, a large stock of anchoveta had been supported by the Peruvian upwelling system and this stock formed the base of the largest fishery in the world. After the collapse, the stock never recovered to former levels. Evidently, it is a worthwhile task to identify "the cause(s)" for the collapse and the nonrecovery of anchoveta, although this may imply a knowledge of the degree to which the observed fluctuations were determined ... "deterministically."

Thus, to summarize the previous considerations: the Peruvian upwelling system may exhibit a variability - at least partly - which is stochastic in character. Furthermore, little is known on the response characteristics of the biological components of the system to external perturbations or to internal instabilities. Thus, it seems appropriate to investigate to which degree the observed changes of the Peruvian upwelling system may be understood as random events. The degree of randomness inherent to the Peruvian upwelling ecosystem will determine the predictability of future changes.

In order to do so, several of the time series of 30 years monthly means, recently made available by Pauly and Tsukayama (1987), will be used. First, some known features of the time series will be interpreted with respect to the stochasticity of the underlying mechanisms. Then, the theoretical background of the hypotheses adopted for further data analysis is given. This is followed by methodological considerations concerning the technique for data analysis.

Preliminary Data Analysis

The following section refers mainly to results of time series analysis on physical parameters as published by Brainard and McLain (1987), Bakun (1987) and Pauly et al. (1987). Most of these time series cover about 30 years by monthly means, with some temporal interpolations.

Seasonality and Anomalies

The parameters to be considered first are the temperature data and the related quantities, such as heat content, isotherm depths and radiation flux. A well-defined seasonal signal is found at the surface and at depths down to about 75 m. At greater depths, e.g., at the depth of the 14° isotherm, the seasonal signal is not visible any longer.

These features are well described by the autocorrelation functions calculated by Brainard and McLain (1987). Fluctuations of the spatially averaged sea surface temperature (SST) are explained to 60% (autocorrelation extreme of about +/- 0.8) by the seasonal cycle. Fluctuations of the local SST, e.g., La Punta and Talara, are explained to about 10% by the seasonal cycle. At depth, e.g., at the depth of the 14° isotherm, 5% of the annual temperature extrema are explained by seasonal fluctuations. This behavior shows that the seasonal signal is generally of limited importance in these depths.

This lesson seems to contradict the impression gained by visual inspection, e.g., of the local SST. However, visual inspection overemphasizes organized structures in terms of variance. Thus, a relatively strong periodic signal superimposed by noise would clearly be seen by eye.

Autocorrelation functions calculated from the time series after subtracting the mean seasonal signal decrease rapidly. The autocohherence drops to values below 0.2 for lags greater than 4 to 12 months, depending on the parameter, and does not increase significantly for longer lags (up to 48 months). The time series of anomalies displays events of the same sign of longer and shorter duration. The amplitudes of these anomalies are, on the average, about one standard deviation. Thus, aside from the seasonal cycle, no other quasi-periodic structure appears to be present in the temperature time series.

The next group of parameters to be discussed concerns wind forcing and sea surface level. Local sea level, Southern Oscillation Index (SOI) and locally and spatially averaged winds show a noticeable seasonal pattern which does not dominate the variance of the time series. Time series of these parameters show, after suppression of the seasonal signal, no well-defined periodic structure. In general, no qualitative differences between these time series and those of the temperature-related parameters are found.

It is common to both groups of parameters that the autocorrelation drops to about 0.7, or less, at a time lag of 2 months. Thus less than 50% of the variance in any month can be explained by the observations 2 months before.

To date, the time series on biological parameters have not been subjected to any analysis similar to those performed with the physical parameters. Visual inspection shows some biannual variability for the anchoveta biomasses and several pulses starting from different background levels. The overall impression is that of a more regular behavior than for the physical parameters, combined with larger amplitudes of the fluctuations.

These observations suggest that most of the variability in the time series is caused by relatively short, not-correlated events. Periodic, mainly seasonal signals, are present but are submerged by a strong background noise. In order to test this, a statistically robust form of spectral analysis has been applied (see below).

Data Preprocessing

Spectral and other analyses have been applied to the SST-related time series (spatial mean temperature and local measurements at La Punta, Callao) as well as to other series: depth of the 14° isotherm, upwelling and turbulence indexes (calculated from spatially averaged winds), offshore Ekman transport, SOI, absorbed solar radiation and VPA-biomass estimates of the anchoveta length classes centered about 4.25 cm (recruits) and 16.25 cm (mature adult fish). It is assumed that the two biological time series contain most physical and nonphysical influences affecting anchoveta. Thus, they are taken as a measure of the integrated response of the ecosystem to natural and anthropogenic (fishery-induced) perturbations.

Table 1 gives the sources of all time series discussed here; these sources provide detailed descriptions of the time series and their derivation from raw data. The period considered, January 1953 to December 1977, excludes the extreme 1982-1983 El Niño and its possible preludes from

the analysis. Furthermore, at least some of the time series on physical parameters seem to have changed their behavior in the late 1970s, compared to the preceding period. Thus limiting the analysis to the period 1953 to 1977 favors stationarity of the derived statistics.

Each time series has been analyzed in four different forms: (i) in its original form but with interpolated missing values, (ii) after transformation as described below, (iii) after differentiating in time by central differences, (iv) after differentiating and transformation.

Differentiating eliminates linear trends. The transformation eliminates the seasonal signal of the time series and normalizes the deviations from the seasonal signal. For transformation, the median-seasonal cycles of the time series have been calculated. In order to get reliable and independent estimates of the medians, three consecutive months were grouped into one season (January, February, March = summer, etc.). Then each data point has been replaced by an index (1,2, ..., 12) indicating the twelfth-quantile (quantile width: 8.33%) to which it belongs. The use of medians and quantiles instead of means and standard deviations is due to the need to calculate robust statistical estimates from non-normally distributed data (Huber 1981). Twelfth-quantiles are used because these describe directly some common statistics data sets. The 95% confidence limits of the medians correspond to the 5/12 and 7/12 quantiles; also, two-thirds of the data are between the 2/12 quantile and the 10/12 quantile.

Fig. 1 shows seasonal cycles of four parameters. The mean seasonal cycle is generally not sinusoidal. Seasonal means of the spatial averaged SST are the same for the periods July to September and October to December. The mean depth of the 14° isotherm is the same from January to September. Upwelling has different strengths in all seasons and mean biomass of mature adult anchoveta shows no seasonal cycle. Deviations from mean conditions dominate the seasonal signal for all parameters. The amplitudes of the deviations from the medians are asymmetric. Thus, means estimated by arithmetic averaging will lead to different estimates of the seasonal cycle. The difference is due to the tendency of the arithmetic mean to minimize the variance.

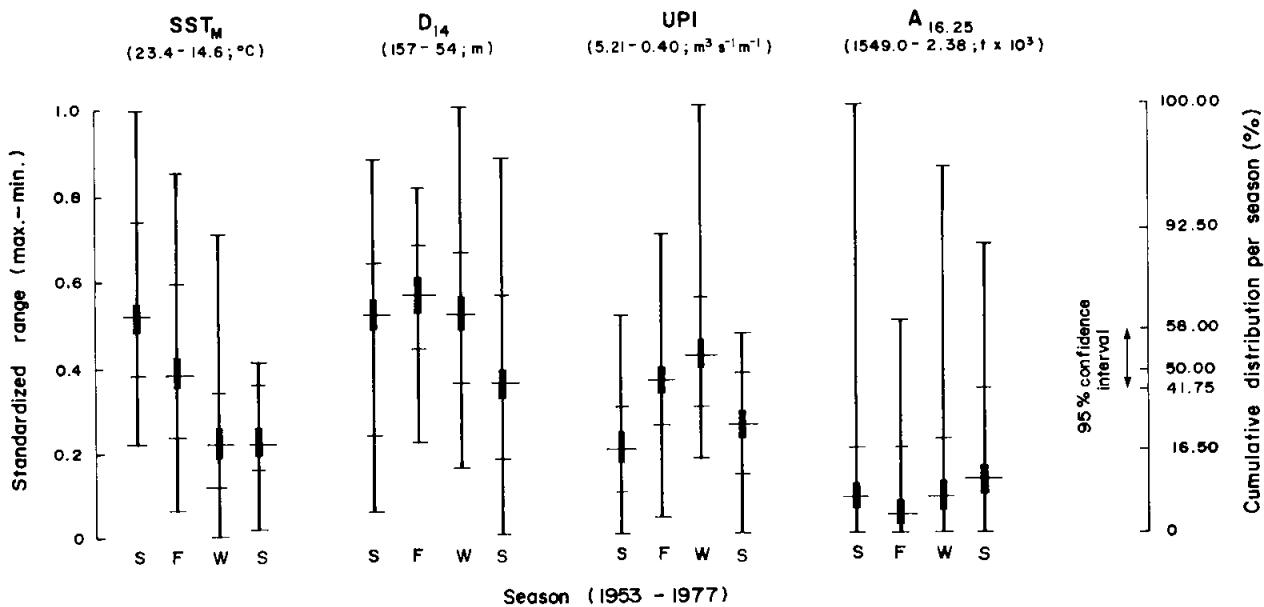

Fig. 1. Examples of the mean seasonal signal shown by the normalized form of four parameters (see Table 1 for definition). The total ranges are shown (top and left scale). The standard errors (bold) refer to the 95% confidence intervals of the medians (see right scale). The seasons (SFWS) refer (from left to right) to months: January-March, April-June, July-September, October-December.

Las estaciones (SFWS) se refieren (de izquierda a derecha) a los meses: Enero-Marzo, Abril-Junio, Julio-Septiembre, Octubre-Diciembre.

Spectral Analyses

The technique used for spectral analysis, a modification of Nuttals' (1971) procedure of short averaged periodograms was used to estimate Fourier transforms of 9 five-year long, prewhitened - recolored and 50% overlapping lags of the time series. Median power spectra and their 95% confidence intervals were calculated, and the slopes of the median spectra were estimated for periods ranging from 60 to 6 months.

The results obtained by the spectral analysis are summarized in Fig. 2 and Table 3. Bands of high variance are identified as "peaks" if the confidence limits do not overlap. The widths of the confidence limits show the variability on the time scales longer than 5 years. The spectra are generally less structured. The variance is distributed continuously over a broad range of periods, a feature typical for time series of random sequences of individual events. No important changes in the main features of the spectra were found when the spectra of the time series themselves were compared to their rates of change. Thus, the time series of the observed variables and their rate of change are similar sequences of random events.

No significant peaks were found, except for absorbed solar radiation "Q" at a period of 12 months. Thus, only this parameter has a clear seasonal signal which covers broadly, including the spectral bandwidths, the period range from 18 to 9 months. All spectra of original time series show bands of high variance centered around a 12-month period. Several spectra show a steplike decrease of variance to shorter periods at periods near to 12 months. Thus, the seasonal cycle is relatively well represented, but cannot be statistically distinguished from the events which form the background signal at neighboring periods. The seasonal fluctuations have high variances but vary so much at longer time scales that they are not statistically different from fluctuations at other periods.

Some spectra of the transformed time series show relatively high, but not statistically different variances for the period range 45 to 25 months. This feature was found for SST,

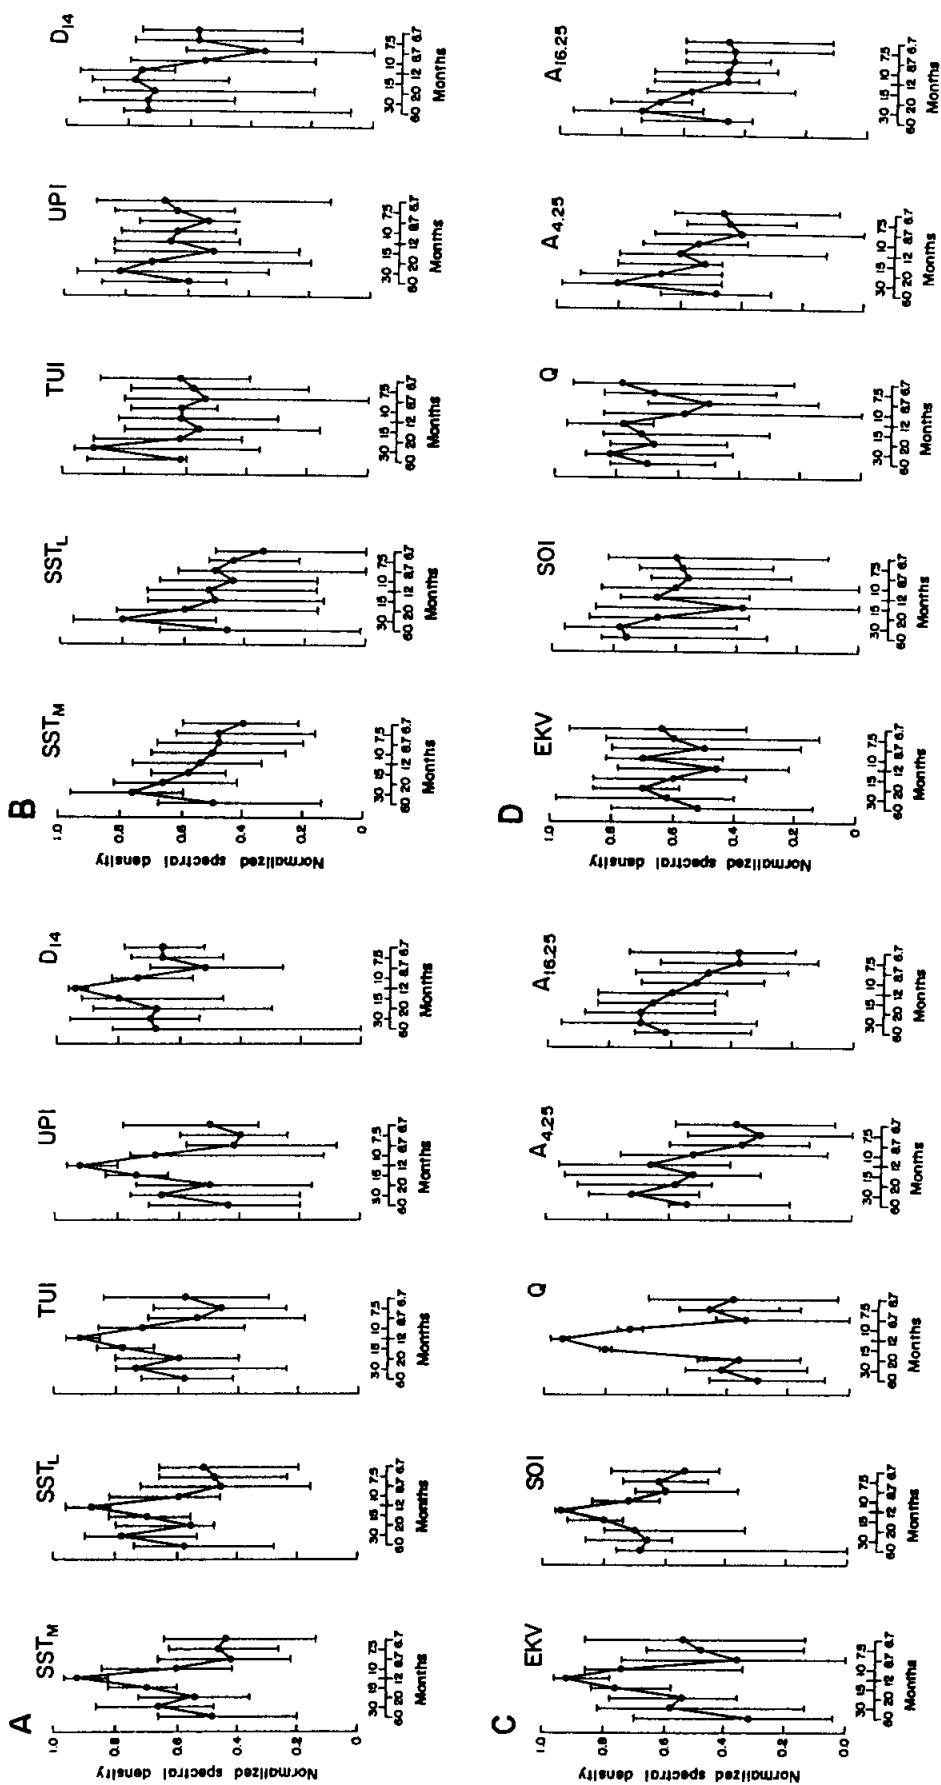

Fig. 2. Mean variance spectra (logarithmic and normalized) showing the 95% confidence interval of the median variance (see Table 3 for further statistics on these spectra). A. Original time series; B. Transformed time series; C. Transformed time series; D. Transformed time series.

anchoveta biomasses, SOI, the turbulence index and to a lesser degree, for the upwelling index also. This signal is most probably due to the mean time interval between two successive El Niño events. Therefore, it should be noted that the spectra of the transformed time series on the depth of the 14° isotherm is flat for periods longer than 12 months. One result of this is that the temporal changes of the temperature structure of the upper layer are different at depth and near the surface. This corroborates similar results obtained by Brink et al. (1983) for motions on shorter time scales.

To summarize: the spectra have properties which are inconsistent with the hypothesis that the time series are composed of a small number of periodic signals. The spectra obtained corroborate the suggestion that the variability of the Peruvian upwelling system should be described as a sequence of random events. Periodic deterministic patterns are of little importance and are probably restricted to the seasonal cycle.

Theoretical Considerations

The results of the preliminary data analyses suggest that a substantial part of the observed changes in the Peruvian upwelling system are due to sequences of random events. Here a mathematical tool will be developed to handle sequences of random events.

The general model

$$Y(x+t) = Y(x) + V * t^a \quad \dots 1)$$

was used (Turcotte 1988). Here, "Y" takes the place of any derived quantity, but could be the observation itself; "x" is the value of the independent variable at the starting point and "t" is its increment; "a" is a constant to be determined, and "V" is a stationary random variable taken from a distribution with unknown moments which, likewise, have to be determined if the process (1) is to be completely described. Thus, equation (1) defines Y by a random process which is nonstationary in t if a is not equal to zero.

If E() is a linear estimator of the expectation, e.g., of the mean, then (1) may be rewritten:

$$E(Y(x+t)) = E(Y(x)) + U * t^a \quad \dots 2.1)$$

$$U = E(V) \quad \dots 2.2)$$

Averaging is done over an ensemble of Y values at different starting points x and same increments t. Thus, E() is an ensemble average and its expected value varies with t^a .

If $E(Y(x))$ is equal to zero, then

$$\ln(E(Y(x+t))) = \ln(U) + a * \ln(t) \quad \dots 3)$$

holds. Equation (3) holds approximately for nonvanishing $E(Y(x))$ if $U * t^a$ is sufficiently larger than $E(Y(x))$.

It can be expected that given values of a and of the statistical moments of V hold only for a limited range of t values. Their lower and upper bounds give the range within which the process (1) is correlated.

Equations (2.1) and (2.2) can now be interpreted on three different levels. First, the equations give only an average power law dependence of Y as a function of t. Second, the equations describe the average geometrical properties of Y as a function of t. Third, they determine the nonstationary mean characteristic of the random process (1).

In order to illustrate the random process characteristics of the model, equation (1) may be rewritten as

$$(Y(t) - Y(0))/(t^a) = V \quad \dots 4)$$

(where the x has been dropped for convenience).

Thus, the normalized increment of Y is a random variable. Equation (4) is identified as a definition of a random walk, if a is equal to 1/2 and V is Gaussian. If a is zero and V is Gaussian, then (4) describes a Gaussian white noise process. Thus, (1) is a generalization of a first order stationary noise process.

The geometrical interpretation can be performed by comparing to the particular forms of (1). First, the "new" value of Y is estimated in "one step":

$$Y(T) = Y(O) + V * Ta \quad ...5.1)$$

and second, the "new" value of Y is estimated in "several steps" (n):

$$Y(n * t) = Y(O) + (V_1 + V_2 + \dots + V_n) ta \quad ...5.2)$$

Both forms of estimation of new values of Y lead to the same expected value of new Y , if

$$a = \ln(n)/\ln(T/t) \quad ...6)$$

holds.

Equation (6) is the definition of the fractal dimension a . Here, a relates the ratio of the scales of increments T and t to the number of repetitive use of the smaller scale to "measure the same object". The object measured is the mean difference between old Y and new Y as a function of the increment of the independent variable.

Using (6) in (5.1) gives the expectation of $Y(T)$ as a function of the small increment t :

$$E(Y(T)) = E(Y(O)) + n * E(V) * ta \quad ...7.1)$$

$$\ln(n) = \ln(T/t) * a \quad ...7.2)$$

Thus, the prognostic of $Y(T)$ done by small steps of length, for example, " $t = 0.1 * T$ " can be done in 10 steps only if a is equal to one.

In consequence, (nearly) any *ad hoc* decomposition of the increment T of a given process (1) into smaller increments will lead to different estimates of its mean characteristics. Commonly used refinements of increments, such as "divide T in two parts of length $T/2$ each" will have no influence on the estimate $E(Y(T))$ only if the process is stationary ($a=0$) or linear ($a=1$). Thus, estimates, e.g., of the mean values will depend on the sampling frequency, for any quantity varying with (1) if the statistical process is neither stationary nor linear.

Summarizing the properties of the model (1): If a is greater than zero and fixed for a given interval of t , then (1) describes a correlated random process which has a mean fractal geometry and is defined for the given interval of t . Thus the process (1) is a "correlated fractal noise process" (CFNP).

Methodological Considerations

The following section briefly discusses the quantities analyzed using the concept of a CFNP, as developed above. Furthermore, the main lines of interpretation and the questions to be answered by the analysis are presented.

Estimates of the nonstationarity of the time series are considered first. Prognostics can be given only if the degree of nonstationarity is known. Second, mean spectral slopes are relevant because CFNP's (time as independent variable) can be identified by their variance spectra (Turcotte 1988). Thus, the contribution of noise processes to the observed fluctuations must be considered. The last quantity analyzed involves the concept of the phase space and the distribution of observations (the phase points) in this space. Here correlation over distance in the phase space and its geometry is used to draw conclusions regarding the interdependence of different parameters, e.g., SST and SOI.

Direct estimates of the exponent a of the CFNP (2.1) are calculated by means of linear regression (equation 3). The slope of the linear regression is evaluated for the widest (centered) interval of the independent variable for which: (1) the square of the regression coefficient is above 0.33 (i.e., explained variance is above 33%), (2) the regression coefficient is statistically different from zero (95% confidence level) and (3) the interval of the independent variable for which the regression holds can be divided in sub-intervals for which conditions (1) and (2) are fulfilled.

Analyses of Nonstationarity

In order to estimate the degree of nonstationarity of the time series, three quantities have been analyzed using the model (1): (i) the difference of mean values calculated from two lagged fractions of the same time series as a function of the lag; (ii) the covariances of two lagged fractions of the same time series minus the variance found for lag zero as a function of the lag; (iii) the number of extrema (minima or maxima) during an observation period of given length as a function of the observations period. Nonstationarity of the time series will show up either via the difference of mean values and of covariances, which depend on the lag, or via the counts of extrema (which do not increase linearly with the length of the observation period).

The variability of mean values and covariances of the time series for lags between 3 to 97 months was analyzed by a technique based on a procedure in McHardy and Czerny (1987). Two fractions of the time series, each about 8 years long, were taken, which are separated by a given lag. The difference of their means and the difference of their covariances are estimated. This procedure is then repeated for about 100 starting points (see equation 1) along the entire time series. The medians of these differences are analyzed as a function of the lag t .

If the averaging period is sufficiently long and if the process which generated the time series has stationary means and covariances, then the differences should vanish (in the statistical sense). The exponent a in equation (2.1) would thus be estimated as zero and $Y(t)$ would be identified as a stationary random variable. Any drift of the differences would reflect a trend, i.e., a nonstationarity of the underlying process. If no functional dependence of the averaged distances exists, then the process (1) cannot be used validly to describe the observed form of nonstationarity.

The number of extrema above or below a given threshold has been counted for periods of increasing length, from 3 to 97 months, as was the median counts for about 100 starting points. The threshold has been defined by either the seasonal 2/12-quantiles or the 10/12-quantile (Fig. 1). Thus, extrema are counted relative to the mean seasonal signal. If the process generating extreme values is stationary, then the counts should increase proportionally with time and a in equation (2.1) should be estimated as one.

Spectral Slopes

The spectral analyses covers the time interval from 5 months to 5 years. Spectra have been calculated as reported above. Then, the mean increase of the median variance as a function of the period was analyzed. In order to do so, a power function was fitted to the spectra for the range of periods from 60 to 6 months. The exponent (b) of the power function of the dependence of spectral variance was related by Turcotte (1988) to the exponent a of the CFNP process (1) via:

$$b = 2 * a + 1 \quad \dots 7)$$

A white noise process is described by a flat variance spectrum, while a random walk process has a variance spectrum that increases in proportion to the period squared. Thus, the spectral slope and the fraction of the explained spectral variance describe, for the interval of periods analyzed, the mean characteristic and relative importance of the process by which the time series has been generated. If no mean slope can be estimated, then CFNP of form (1) do not contribute to the observed time series.

Distribution of Phase Points

This analysis starts from the concept of the phase space. Two variables observed at the same time or one variable and its rate of change can be plotted as a function of each other. The surface defined by this procedure can be understood as a (two-dimensional) phase space. The observations are the discrete representation of the phase line (Fig. 3). A cyclically changing variable and its rate of change or two variables which are out of phase but have a fixed phase lag would define a closed loop (i.e., a phase cycle) in the phase space. Less well correlated variables would define a cloud of points in the phase space. Here, only one case of a phase cycle has been found; it pertained to absorbed solar radiation and its rate of change. All other clouds of phase points scattered without structure over the phase space.

The mean geometrical structure of the clouds of phase points was analyzed using the approach of Lovejoy et al. (1986). If two independent random variables are plotted against each other, then their scatter plot will show no internal structure. Furthermore, the phase points of two parameters related in complex fashion will be scattered over their phase space likewise such that no internal structure is apparent (Fig. 3). However, not all combinations of values of two such parameters are possible. Thus, there are areas in the neighborhood of a given phase point which will never include a phase point. Thus, the phase space is a patchwork of voids, forbidden regions, and of phase lines along which the phase points are distributed. Therefore, subregions of the scatter plot with high and low density of points will be found, and the number of points found in the neighborhood of a given point will increase in proportion to the power of less than two (i.e., the square of the distance). Thus the local dimension of the scatter plot of phase points will differ from two.

The quantity to analyze, in accordance with the CFNP model (1), is the average number of phase points within a circle of a given radius as a function of the radius. The phase space defined by the observed minima and maxima of the parameter has been divided in M cells, M being equal to the number of observations (N) squared. Thus, two parameters depending upon each other in strictly linear fashion will tend to form a phase line along a diagonal of the phase space. In this case, the number of points within a circle of a given radius increases proportionally to the length of the radius. If, on the other hand, the phase points were distributed regularly on a cartesian grid, counting the number of points within circles of increasing radius (large increase compared to the grid spacing) would show that the number of points increases proportionally to the square of the radius. Thus, if the distribution of phase points on the cartesian grid is done

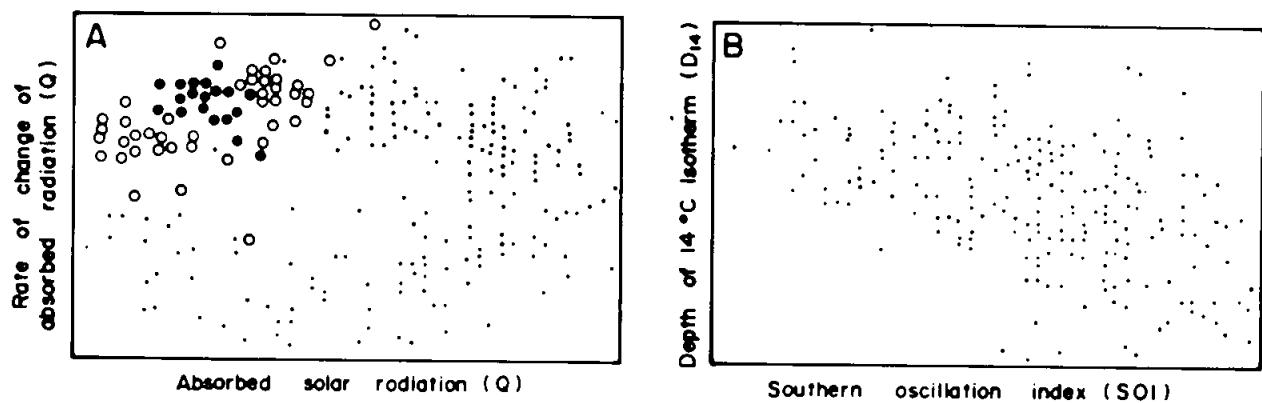

Fig. 3. Two examples of a two-dimensional phase space, as defined by two parameters each. Note the roughly circular structure of the phase points of the phase space for rate of change of absorbed solar radiation vs. absorbed solar radiation. (Closed circles represent August observations; open circles represent July and September observations; small dots represent the other observations).

Fig. 3. Dos ejemplos de un espacio de fase bidimensional, definido por dos parámetros. Notar la gruesa estructura circular de los puntos del espacio de fase para tasas de cambio de radiación solar absorbida contra radiación solar absorbida (círculos llenos representan observaciones en Agosto; círculos vacíos representan observaciones en Julio y Septiembre; los puntos representan otras observaciones).

regularly (in the statistical sense), then the square dependence of the number of points within the circle defined by a given radius will be recovered, on the average.

Two estimates of the mean dimension of the cloud of phase points are given here, one for lengths of radius ranging from $0.1 * N$ cells to $0.9 * N$ cells (long radius, $R_{(G)}$, or "global" dimension), and the second for the range $0.015 * N$ to $0.15 * N$ cells dimension (short radius, $R_{(L)}$, or "local" dimension). In order to avoid strong border effects, the reference points from which the counting procedure start are those phase points whose coordinates lie within the range given by the seasonal 4/12-quantiles and 9/12-quantiles.

Comparing the (fractal) dimensions of phase spaces defined by different parameters then shows which parameters are more closely related than others. The "global" and the "local" geometry of the cloud of space points is estimated by the dimensions for long ($R_{(G)}$) and short ($R_{(L)}$) radius lengths. Dimensions of about two will be found for space points which are evenly distributed. The interpretation is that the investigated pair of parameters is not related and that any combination of values is possible. Dimensions somewhere between about one and less than two will be found for space points which are distributed along intersecting lines. The interpretation is that many but not all combinations of a pair of parameters are possible. Dimensions below one will be found for space points which cluster in disjoint patches. The interpretation is that only few parameter combinations can occur.

Results and Discussion

Stationarity

Table 2 gives the results of the six different tests of stationarity of the time series and their rate of change which have been performed.

The overall ratio of "failed" to "passed" is 91 to 29. This ratio is biased toward "failed" because some of the observed nonstationarities cause only small effects. Therefore, some "failed" cases might be classified as "practically stationary". However, discussing this further would involve arguments on the range of nonstationary changes which are acceptable. It seems to be reasonable to rely only on those criteria (for accepting a regression) which have been presented above. Therefore, we conclude that temporal changes of the Peruvian upwelling system are mainly nonstationary. Three details should be mentioned, however, which qualify this statement:

- (i) 8-year means are nonstationary for all time series and all derived time series, whether they have been transformed or not (by eliminating the seasonal signal and normalizing the fluctuations). Thus, stable mean values characterizing the Peruvian upwelling system need averaging over periods considerably longer than 8 years to eliminate the influence of long-lasting anomalies.
- (ii) the covariances of the transformed time series are generally stationary, the single exception being absorbed solar radiation. The covariances of original time series are stationary for all temperature-related series (SST_M , SST_L , D_{14}), for upwelling (UPI) and for the biomass of anchoveta recruits ($A_{4.25}$). Thus, covariances characterizing the variability of the Peruvian upwelling system might be estimated from 8-year-long records - at least after elimination of the seasonal signal and normalization of the anomalies.
- (iii) the least stationary parameter seems to be the SOI; only the covariance of its transform is stationary. However, the frequency of "failed" cases varies only slightly between all parameters beside local sea surface temperature (SST_L) and biomass of anchoveta recruits; the latter is the most stationary parameter. The stationarity of the least two parameters is documented, in spite of changing mean values, by the occurrence of extreme values in the original series, in their rate of change and in the covariances.

Noise-like Temporal Structure

The spectra shown in Fig. 2(A-D) have previously been discussed in relation to the importance of the seasonal signal and the variability on periods longer than 5 years. Here the mean increase of variance in function of the period is discussed because these "spectral slopes" are related to special forms of CFNP's (Table 3). This type of model was used to qualify the random events which contribute to the temporal structure of the time series. The CFNP is accepted as relevant if it describes more than 1/3 of the variance of the time series.

It was found that no original time series of physical parameters fit the CFNP-concept (Figs. 2A and 2C). However, both VPA-biomass time series do. This is due to the seasonal signal which appears more important in the physical data than in the biomasses. Transformed time series of SST's, depth of the 14° isotherm (D₁₄), SOI and VPA-biomasses may be described by CFNP's (Fig. 2B and 2D). It should be noted that all physical parameters linked to

Table 3. Confidence intervals of slope (b) and coefficient of determination (r^2) of linear regressions analysis of variance spectra in Fig. 2 (A-D), i.e., of linear plots of log (variance) vs. log period.^a
Tabla 3. Intervalo de confianza de la pendiente (b) y el coeficiente de determinación (r^2) del análisis de regresión lineal de espectros de varianza en la Fig. 2 (A-D), es decir, de gráficas lineales de log (varianza) versus log (período).

^aResult in this table refers only to significant correlations ($P < 0.05$).

^bSee Table 1 for definitions.

meteorological forcing, e.g., the upwelling index, show no structure which can be described by CFNP's.

Overall, CFNP's describe about half of the variance (42%-66%) of the time series and all spectral slopes are significantly different from zero. Consequently, the CFNP's are different from white noise processes which are characterized by a vanishing slope of the variance spectra. The slopes of the different spectra are, due to the wide confidence limits (95% level), not significantly different from each other and from a slope of one. Thus, details on the nature of the CFNP's cannot be given beyond stating that it is near-brownian (fractal brownian in the notation of Turcotte (1988)). Therefore, equation (1) may take for SST, 14° isotherm depth, SOI and the VPA-biomasses the form:

$$Y(t+x) = Y(x) + V * t^a; a \geq 0 \quad ...8)$$

However, there is a tendency towards steeper spectral slopes for the VPA-biomasses compared to the physical parameters; this may lead to slightly different exponents in equation (8).

In summary, the main characteristics of the temporal behavior of the parameters analyzed are: (i) parameters related to meteorological forcing (upwelling index, turbulence index, Ekman transport and absorbed solar radiation) are characterized by seasonal variations and an unspecified noise process; (ii) the parameters describing the thermal structure of the upper layer of the Peruvian upwelling system (SST's and depth of the 14° isotherm) are characterized by seasonal variations and a correlated fractal noise process (CFNP) which is of near-brownian nature; (iii) the biological parameters (VPA-biomasses of recruits and of mature adult fish) are characterized by CFNP of near-brownian nature.

Interrelationships Between Parameters

The interrelationship of parameters can be measured, as discussed above, by the dimension of a cloud of phase points. Two estimates of the dimensions have been calculated, a "local"

estimate ($D(R_L)$) for small regions and a "global" estimate ($D(R_G)$) characterizing the whole phase space. These two dimensions (including confidence limits) characterize the cloud of space points of each pair of parameters. Their values are used to define a "point" in a scatter diagram of "global dimension vs. local dimension". Fig. 4 presents the possible pairs of parameters, as ordered in three different groups.

Fig. 4A presents all pairs of parameters which are evidently a function of each other. These pairs are: (i) "parameter against its rate of change"; (ii) "two parameters derived from the same data"; and (iii) "mean SST_M vs. local SST_L ". In Fig. 4A, the global dimensions scatter between 0.25 and 1.5 and the local dimensions scatter between 1.00 and 2.00. This indicates that the phase spaces are unevenly covered with phase points, voids are present, but subregions of some phase spaces are found which are evenly covered by phase points (local dimension near two).

For example, the phase space defined by the absorbed solar radiation (Q) and its rate of change (see Fig. 3A) has a global dimension of about 1.35 - 1.40 and a local dimension of about 1.75 - 1.80 (see Fig. 4A). The phase points in some small subregions of the phase space are more evenly distributed than all phase points over the entire phase space. The corners and the central

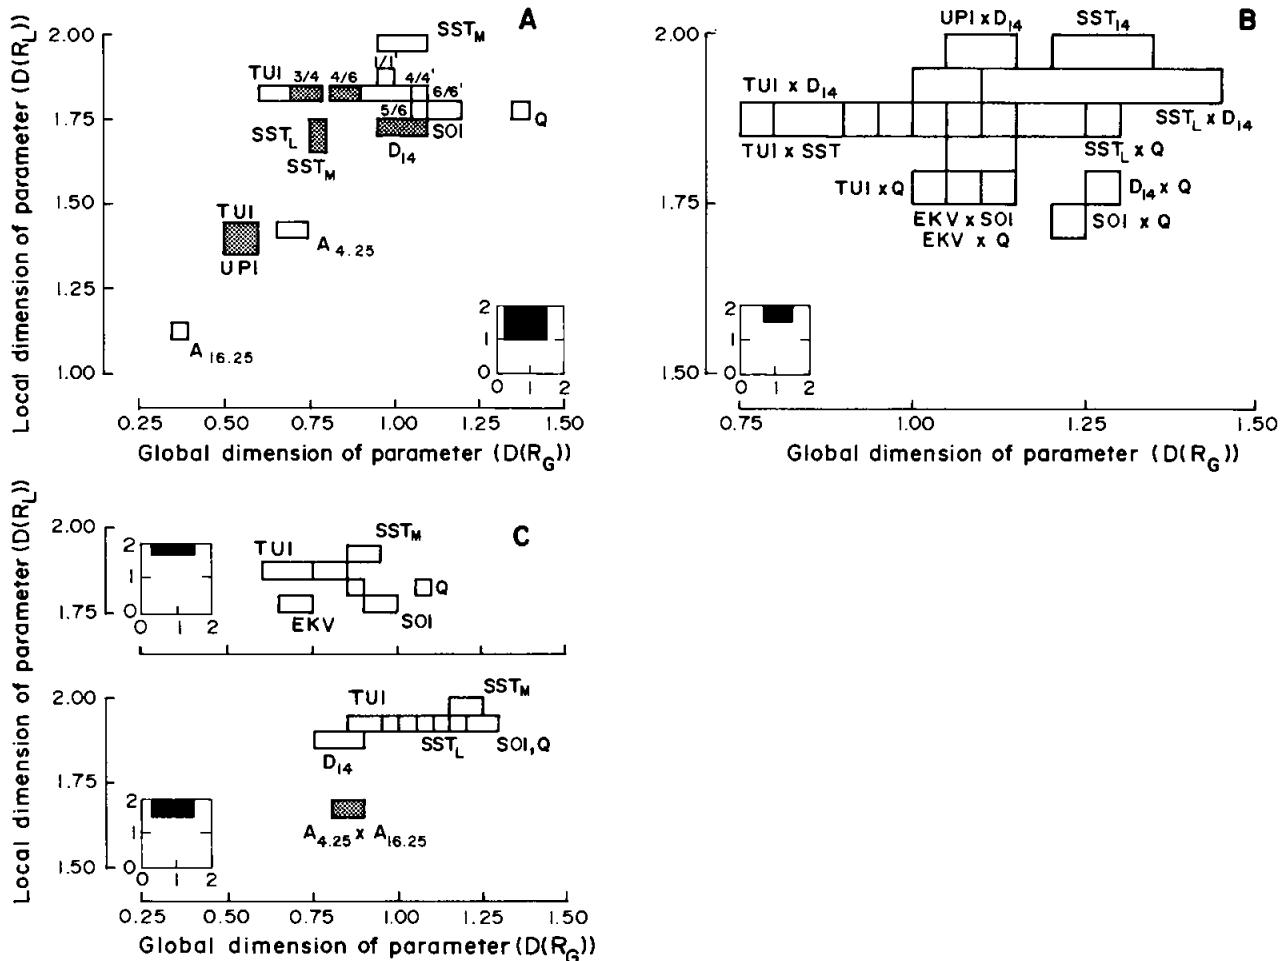

Fig. 4. Plots of the local dimension ($D(R_L)$) of various parameters vs. their global dimension ($D(R_G)$). The insets define the possible range of dimension, and the range actually occupied (black rectangles). Some rectangles and/or squares are not labeled, due to space limitation. A. Pairs of parameters were derived from the same databases (shaded rectangles) or one is the rate of change of the other (open rectangles). B. Same as A, but referring to unrelated parameter pairs (different databases, no differentiation). C. Same as A, but for "biological" vs. "physical" parameter pairs. Upper graph: physical parameters vs. biomass of anchoveta with length of 16.25 cm ("adults"). Lower graph: physical parameters vs. biomass of anchoveta with length of 4.25 cm ("recruits").

Fig. 4. Gráficas de la dimensión local ($D(R_L)$) de varios parámetros contra su dimensión global ($D(R_G)$). Los insertos definen los rangos de dimensiones posibles, y el rango realmente ocupado (rectángulos negros). Algunos rectángulos y/o cuadrados no están rotulados, debido a limitaciones de espacio. A. Pares de parámetros fueron derivados de la misma base de datos (rectángulos sombreados) o uno es la tasa de cambio del otro (rectángulos vacíos). B. Lo mismo que en A, pero refiriéndose a pares de parámetros no relacionados (diferente base de datos, sin diferenciación). C. Lo mismo que en A, pero para pares de parámetros "biológicos" versus "físicos". Gráfica superior: parámetros físicos versus biomasa de anchoveta con longitudes de 16.25 cm ("adultos"). Gráfica inferior: parámetros físicos versus biomasa de anchoveta con longitudes de 4.25 cm ("reclutas").

region of the phase space is nearly empty of phase points (see Fig. 3A). It is concluded that most surface points of the phase space in the neighborhood of a given phase point are possible phase points. The number of voids, or forbidden regions, is relatively small. Thus, future observations of the amount of absorbed solar radiation and its rate of change will be most probably "anywhere near" already observed combinations. However, very different values of one parameter should often go together with different values of the other parameter. These features are expressed by (i) the local geometry of the cloud of phase points - which is roughly a surface and (ii) a global geometry i.e., network of multiple crossing phase lines and voids (forbidden regions).

The ensemble of phase space dimensions of the pairs "physical parameter against its rate of change" in Fig. 4A has a clear main pattern: the global and local dimensions are about 1.0 and 1.8, respectively. These values characterize a phase space which is mainly void on the global scale, but with phase points that are quasi-evenly scattered (local dimension near two) along continuous phase lines (global dimension about one). Different characteristics are found for the phase spaces of the anchoveta biomass, the turbulence index, absorbed solar radiation and spatially averaged SST_M .

The highest local dimension is found for SST_M . This phase space is, on the local scale, evenly covered by phase points (local dimension of two). The local geometry of the cloud of phase points corresponds to a surface. Slightly different values of SST_M are compatible with any slightly different value of its rate of change. The highest and lowest global dimensions for the physical parameters are found for the absorbed solar radiation and the turbulence index, respectively. The phase points of absorbed solar radiation (global dimension well above one) are distributed along multiple crossing phase lines, but for the turbulence index (global dimension less than one) the scatter is around disjunct subregions of the phase space, each indicating a different level of turbulence (strength and rate of change).

The local dimensions of the phase spaces defined by the anchoveta biomasses and their rates of change are relatively small (between 1.10 and 1.45). This suggests that the local geometry of the cloud of phase points does not correspond to a surface, but to a mixture of crossing phase lines and voids, forbidden regions. Thus, the rate of changes of the anchoveta biomasses depend strongly on the biomasses and not all combinations are possible. The global dimensions of the phase spaces defined by the anchoveta biomasses are less than one. This describes the global structure, or geometry, of the cloud of phase points as composed of disjunct sub-clouds, each indicating a different level of the anchoveta stock (biomass and its rate of change).

The combination of local and global features which distinguish the biological parameter from the physical parameter are most pronounced for the biomass of mature adult anchoveta. It might be suspected that the VPA-algorithm is the cause of this different behavior. This argument may be partly correct, but it fails to explain the very different dimensions found for mature anchoveta and anchoveta recruits. Thus, the small dimensions of the phase spaces defined by the biological time series may not be an artifact.

Fig. 4A shows a second ensemble of dimensions, those obtained from parameters which are linked through the data used for their estimation. Most estimates of local and global dimensions scatter for these parameters around 1.75 and 0.90, respectively. These dimensions are smaller than those obtained for parameter pairs which have no common database (in Fig. 4B). What these dimensions measure, however, is the distortion caused either by the mathematical procedure or by the combination of two independent data sources. The individual estimates, as given in Fig. 4A, show: (i) the "blurring" of an unequivocal relation on the local scale (local dimension greater than one) and (ii) a disruption of this relation on the global scale (global dimension less than one). Lower local and global dimensions than those given above are found for turbulence index vs. upwelling index. This is not surprising since both are closely related (via the winds used to compute both) and do not depend on a third parameter.

Fig. 4B shows the local vs. global dimensions for phase spaces defined by two independently determined physical parameters (of which an example is shown on Fig. 3B). The local and global dimensions scatter around 1.85 and 1.10, respectively, which is not very different from the dimensions of phase spaces defined by dependent physical parameters as discussed above. However, the differences are important when individual pairs are considered.

- (i) local dimensions not statistically different from two are found for the parameter pairs upwelling index versus 14° isotherm depth and mean SST vs. absorbed

global radiation. Thus, for these parameter combinations, any point of the phase space near a given phase point is a possible phase point, or conversely, there are no voids in the neighborhood of any phase. Global dimensions for these two parameter pairs are about 1.1 and 1.3. Thus, both phase spaces are covered by phase points scattering evenly along multiple crossing phase lines separated by voids. It follows from this that small changes of one parameter, e.g., upwelling index, are consistent with any small change of the other parameter, e.g., 14° isotherm depth (D_{14}).

- (ii) small global dimensions (about 0.8), combined with relatively high local dimensions (about 1.85), are found for the parameter pairs "turbulence index" vs. "local SST" and " 14° isotherm depth", respectively. Therefore, the geometry of the clouds of phase points is determined by disjunct subclouds of nearly evenly scattered phase points. Local geometries have only a small amount of voids, but global geometries consist of disjunct states. Therefore, these two parameter pairs best characterize different physical states (or large changes) of the system as a whole.
- (iii) small local dimensions (about 1.75) and relatively high global dimensions (about 1.25) are found for the parameter pairs absorbed solar radiation vs. 14° isotherm depth and vs. SOI, respectively. Small local dimensions (about 1.75) and relatively small global dimensions (about 1.1) are found for the parameter pairs turbulence index vs. absorbed solar radiation and vs. SOI, respectively. The geometry of these clouds of phase points is locally and globally a network of multiple crossing phase lines separated by voids. Thus, these pairs of parameters characterize best different physical states (or small changes) on the local scale.

The dimensions of the phase spaces for the parameter pairs anchoveta biomasses vs. anchoveta biomass or each other vs. physical parameter are shown in Fig. 4C. The main feature of Fig. 4C is that local and global dimensions are mostly above 1.75 or in the range 0.75 to 1.25, respectively, and that the estimates for single pairs of parameters differ considerably.

The local and global dimensions of the phase space defined by the VPA-biomasses of adult, mature anchoveta and of anchoveta recruits are about 1.65 and 0.85, respectively (Fig. 4C). These estimates indicate on the global scale a pattern of different disjunct states. Different combinations of biomasses are possible on the local scale, but forbidden combinations (voids) in the phase space, are important. Indeed, they are more frequent than for all but one pair of physical parameters. However, the combination of the VPA-biomasses on the local scale is not unequivocal and the phase points scatter along multiple crossing phase lines.

The dimensions of the clouds of phase points for the parameter pairs VPA-biomass of anchoveta recruits vs. physical parameter show a clear pattern (Fig. 4C). Highest local and global dimensions, 2.0 and 1.2, respectively, are found in conjunction with SST_M . The lowest local and global dimensions, 1.85 and 0.8, respectively, are found in conjunction with the depth of the 14° isotherm. All other combinations have dimensions between these two limits, which cover a considerable range for the global scale (but not for the local scale).

Thus, on both the global and on the local scale, VPA-biomasses of anchoveta recruits are related most closely to the depth of the 14° isotherm than to any other physical parameter. The second best relation is found for the turbulence index. There, the global dimension is below one, indicating that the phase space is composed of different disjunct states. One should remember that both the 14° isotherm depth and the turbulence index are spatial averages. The least pronounced relations between anchoveta recruits and a physical parameter occur in conjunction with SOI, SST_M , absorbed solar radiation, SST_L , in this order..

The dimensions of the clouds of phase points for the parameter pairs "VPA-biomass of mature, adult anchoveta" vs. "physical parameter" show a more complex pattern than described above. All local or global dimensions range between 1.75 and 1.95 or 0.6 and 1.1, respectively. The highest or lowest local dimensions are found for SST_M or offshore Ekman transport and SOI, respectively. The highest or lowest global dimensions occurred in conjunction with absorbed solar radiation or turbulence index and offshore Ekman transport, respectively.

Thus, the VPA-biomass of the mature, adult anchoveta is most closely related to offshore Ekman transport if global and local scale are considered. The weakest relation of local and

global scales to physical parameters is found for SST_M . On the global scale, the relation is closest or weakest for the turbulence index or the absorbed solar radiation, respectively. Considering local scales, then the relation with anchoveta VPA-biomass is closest for offshore Ekman transport or SOI.

Overall Summary and Discussion

The results relevant to the problem of predictability of the Peruvian upwelling ecosystem can be summarized as:

- (i) The autocorrelations of the physical parameters describing the Peruvian upwelling ecosystem decay rapidly if the seasonal signal is eliminated from the data. On the average, less than 50% of the variance can be explained when the time lag between the observations exceeds two months. This suggests that random events are superimposed on the seasonal cycle.
- (ii) The variance attributable, via spectral analysis, to the seasonal signal, is relatively high only for physical parameters, but does not rise significantly above the variance of the noisy background for all but one parameter - absorbed solar radiation. Interannual variability and long periodic modulation of the seasonal signal dominate over the seasonal signal itself.
- (iii) The seasonal signal is the only quasi-periodic contribution to the time series. Quasi-regular contributions on longer time scales, i.e., El Niño events, were noticed in some time series as a spectral band of high variances. This feature is shown by the anchoveta biomasses, the SOI, the turbulence index and the SST but not by the time series of the depth of the 14° isotherm. This indicates temporal changes in the vertical structure of the upper oceanic layer which differ between single El Niño events. This is a feature which is corroborated by the observation (J. Mendo, pers. comm.) that the composition of the multispecies fish stock off Peru differs between single El Niño events.
- (iv) The characteristics of those noise processes which determine meteorological parameters (upwelling index, turbulence index, Ekman transport and absorbed solar radiation) were not identified, but these processes differ from white noise. Noisy processes describing parameters relevant to the thermal structure of the upper layer of the Peruvian upwelling system (SST's and depth of the 14° isotherm) are identified to be partly (50%) a correlated fractal noise process (CFNP) of near-brownian nature. The biological parameters (biomass of recruits and of mature adults) are also characterized by a CFNP of near-brownian nature.
- (v) None of the time series can statistically be described as stationary. This implies that the Peruvian upwelling system is unsteady in its major characteristics, at least on medium time scales. An exception to this is recruitment of anchoveta, which shows stationarity with respect to its mean variability (variance), the occurrence of extreme increases or decreases and the occurrence of high values. This result suggests an adaptation of the anchoveta to a nonstationary, variable environment.
- (vi) The basic geometry of phase spaces (parameter and its rate of change) of all physical parameters (except the turbulence index) is about the same. The phase points scatter along multiple crossing phase lines separated mainly by voids on large scales. A different geometry of phase spaces is found for the VPA-biomasses and the turbulence index. There, the phase points scatter around disjunct phase states and voids are found on all scales. That is, the number of possible combinations of, e.g., anchoveta biomasses and its rate of change, is smaller than combinations of, e.g., for SST and its rate of change. This implies that anchoveta biomasses and turbulence index are more frequently "locked" in some distinct phase states than the other parameter.
- (vii) Different states of the physical subsystem of the Peruvian upwelling index are best described by the parameter pairs turbulence index vs. local SST or depths of the 14° isotherm, respectively, if large changes of the system are to be analyzed.

For small changes, the pairs of parameters to be used should be absorbed solar radiation vs. depths of the 14° isotherm or SOI, respectively. If both large and small changes of the Peruvian upwelling system must be described, then parameter pairs such as turbulence index vs. absorbed solar radiation, offshore Ekman transport vs. absorbed solar radiation, and offshore Ekman transport vs. SOI are most suitable.

- (viii) The phase spaces defined by the biomasses of mature, adult anchoveta and of anchoveta recruits have a geometry which, on the global scale, reflects disjunct states. Local scale geometry is that of phase points scattering along multiple crossing phase lines, separated by forbidden combinations or voids. The interrelation of the two VPA-biomasses is strong if compared with those of most physical parameters.
- (ix) On the global and local scales, the biomasses of anchoveta recruits and of mature adults are related most closely to the turbulence index (for both VPA-biomasses) or to the depth of the 14° isotherm and the offshore Ekman transport, respectively. Both VPA-biomasses are related most weakly with SST_M .

Fluctuations of the Peruvian upwelling system occurring on time scales longer of more than half a year are, in the mean, a mixture of a seasonal signal and of a nonstationary random process with drifting means and variances. The random process has, in part, a fractal geometry (CFNP).

The analyses of the phase spaces defined by the available parameters yield two major features describing the Peruvian upwelling ecosystem: (i) multiple disjunct states are most characteristic of the dynamics of the anchoveta VPA-biomasses and (ii) physical parameters, e.g., the turbulence index, were identified which are most closely related to biological changes. These parameters are not those which are commonly observed to characterize El Niño, e.g., SST and SOI.

These results are consistent with those interpretations which have been developed by only looking at the time series and inferring the basic principles of the underlying dynamics. The theoretical background, mainly the fractal geometry of the noise processes, proved to be helpful to describe the observations and to understand some principles of the relevant dynamics. The detailed data analyses showed that 30 years of data may be a lower limit for the amount of data needed to describe the Peruvian upwelling system. Thus, efforts should be done to extend other existing, but generally shorter time series (e.g., on sardine or zooplankton biomasses) to a period of at least 30 years.

The main lesson learned is that we can answer the question implied by the title of the book edited by Pauly and Tsukayama (1987): "Why three decades of change?" The answer - "random events determine, to an important degree, the changes of the physical properties of the Peruvian upwelling system" - may restrict our ability to predict future changes.

Abstract

Maps of the seasonal distribution of waters $\leq 17^{\circ}\text{C}$ and of the 20°C isotherm off Peru were analyzed by planimetry. The resulting values were used to derive a set of relationships linking sea surface temperature and size changes of the habitat of anchoveta (*Engraulis ringens*). These analyses show that anchoveta density and hence availability to the fishery are closely correlated to the offshore and alongshore extent of waters $\leq 17^{\circ}\text{C}$.

Resumen

Los mapas de distribución estacional de las aguas frente al Perú con isotermas $\leq 17^{\circ}\text{C}$ y las de 20°C fueron analizados mediante planimetría.

Los valores resultantes fueron utilizados para derivar una serie de relaciones con la temperatura superficial del mar y los cambios en tamaño del habitat de la anchoveta (*Engraulis ringens*). Estos análisis muestran que la densidad de la anchoveta y por ende su disponibilidad a la pesquería están estrechamente correlacionadas a las extensiones a lo ancho y a lo largo de la costa de las aguas $\leq 17^{\circ}\text{C}$.

Introduction

Sea surface temperature (SST) data have turned out to be rather helpful for modelling biological response (metabolism, feeding, migration) of the principal species of fishes, sea birds and sea mammals in the Peruvian upwelling ecosystem (Villavicencio and Muck 1985; Muck and Vilchez 1986; Muck and Pauly 1987; Muck and Fuentes 1987; Muck and Sánchez 1987; Muck et al. 1987). Moreover, the recently published catalogue of oceanographic data for the

*PROCOPA Contribution No. 91.

Peruvian coast (Urquiza et al. 1987) allows detailed, spatially structured analysis of temperature-related parameters, such as area, size and geographical extension of water masses associated with important biological features. One example of such analyses involves the dynamics of the 17°C and 20°C isotherms for describing the distribution area of anchoveta (*Engraulis ringens*) and the inshore offshore migration of its most important predators, mackerel (*Scomber japonicus*) and horse mackerel (*Trachurus murphyi*).

The waters $\leq 17^{\circ}\text{C}$ are the cold and nutrient rich waters of the coastal upwelling ecosystem, i.e., the habitat of the anchoveta. The 20°C isotherm is, on the other hand, the boundary of relatively nutrient poor oceanic water masses of the outer part of the continental shelf, where the bulk of the mackerel and horse mackerel biomass generally occurs (Muck et al. 1987).

Thus, seasonal and El Niño-related changes in the location and/or extent of these different habitats will result in changes of (i) anchoveta concentration, (ii) spatial overlapping of anchoveta predators with their prey, and (iii) mixing of cold, nutrient rich with warm, nutrient poor waters, affecting anchoveta vulnerability for predation and fishery, primary production and temperature-related metabolic rates.

Fig. 1 presents false color satellite images showing SST during (a) a period when cold waters stretched all along the Peruvian coast, and (b) during an El Niño event. Such images, although extremely instructive, are usually costly to obtain, analyze and manipulate. As an alternative, the present contribution presents derivations of simple, linear SST-based models for estimating (1) the size of the area $\leq 17^{\circ}\text{C}$ off Peru, (2) the offshore and alongshore extent of this area and (3) the offshore distance of the 20°C isotherm, our aim being to provide a tool for modelling purposes, e.g., to estimate the vulnerability of anchoveta.

Materials and Methods

The areas and offshore/alongshore distances have been estimated by planimetric analysis of maps published in Urquiza et al. (1987), wherein oceanographic conditions (temperature, salinity, oxygen) off Peru are described on a seasonal basis (i.e., for January-March, April-June, etc.) for the period 1970-1985. Values referring to coastal stretches other than 4-14°S have not been used for the correlation and regression analyses.

The monthly SST values in Pauly and Tsukayama (1987) for the area 4°-14° have been updated (based on IMARPE, unpublished data) and used to compute seasonal means.

Results and Discussion

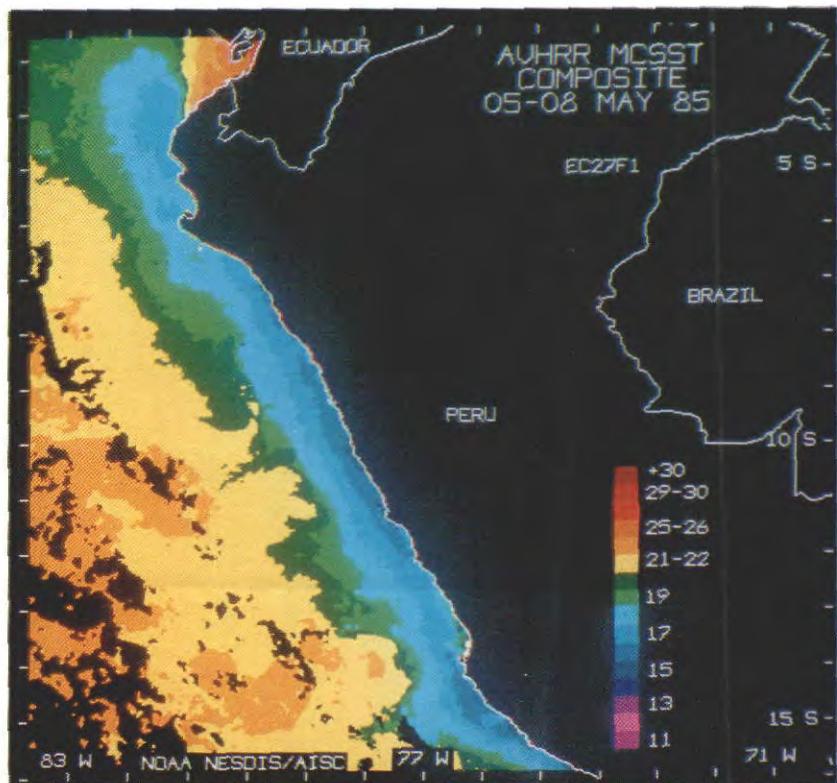

Table 1 gives seasonal means of SST for the entire Peruvian coast and the results of the planimetric analyses of 48 temperature maps (Urquiza et al. 1987). Documented are the size of the area $\leq 17^{\circ}\text{C}$, its offshore and alongshore extent and the offshore distance of the 20°C isotherm.

The results of the correlation and regression analyses (Fig. 2 A-E and Table 2) demonstrate that SST data can be used for estimating the location of the 17°C and 20° isotherms along the Peruvian coast. Fig. 3 presents seasonal means of these parameters for the period 1970-1985.

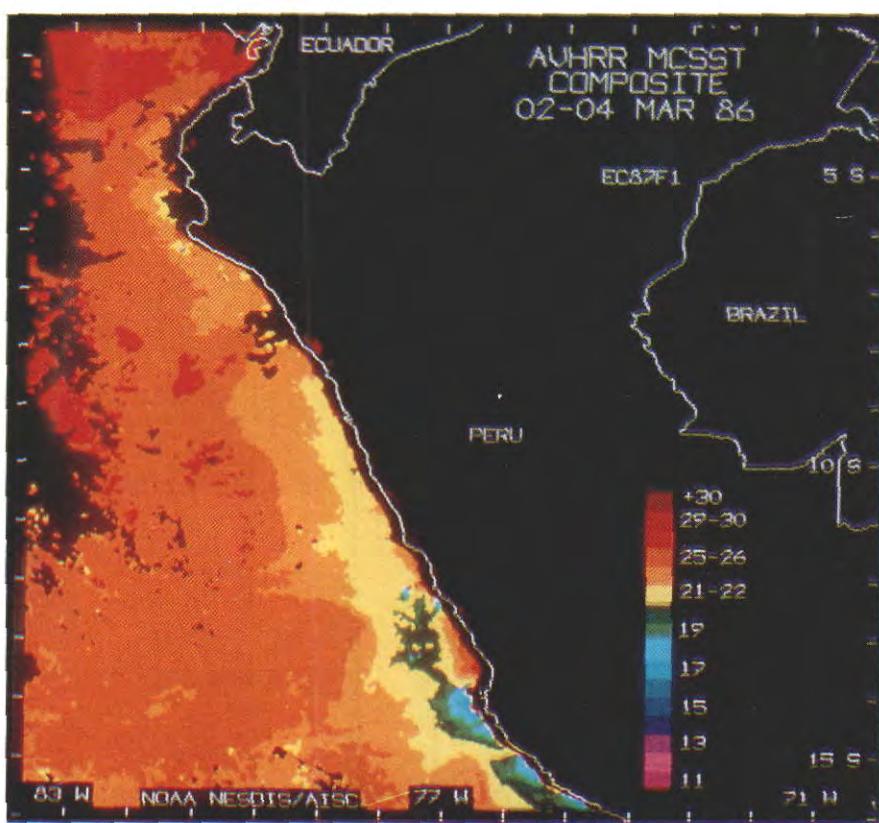

The dynamics of the area of waters $\leq 17^{\circ}\text{C}$ and the offshore/alongshore extent of the 17°C and 20°C isotherms, are as follows: when the overall coastal sea temperature is high (summer, i.e., January-March), the cold area is located at the center and the south of the Peruvian coast, and has a minimum extent and an offshore limit of less than 10 nautical miles. The 20°C isotherm similarly comes close to the coast about 25 nautical miles offshore.

During winter (July-September) most of the Peruvian coastal waters are cold ($\leq 17^{\circ}\text{C}$); this zone has a mean offshore extent of 60 nautical miles and a total area ca. 50 times that occurring in summer. The 20°C isotherm is far offshore (over 100 nautical miles). Spring and autumn have characteristics intermediate between those of summer and winter.

During the El Niño of 1982-1983 the normal seasonal pattern was disturbed. There was no cold water area off Peru from spring 1981 to autumn 1983. During this period the 20°C isotherm

n = The number of isotherms of 17°C and 20°C that were measured per season.

came steadily closer inshore, from 300 nautical miles offshore distance in winter 1981 to zero in summer 1983.

We conclude that mean values of SST data referring to the entire Peruvian coast can be used for estimating the location of the $\leq 17^{\circ}\text{C}$ and 20°C isotherms, which have been considered as characteristic for (i) the cold coastal upwelling area and (ii) the warmer oceanic waters of the outer half of the continental shelf.

Referring to species habitats, 17°C represents the mean preferred sea temperature of anchoveta and 20°C that of mackerel and horse mackerel (Zuta et al. 1983).

Increases in SST, during summer or El Niño events, are correlated with:

- an onshore movement of the 17°C and 20°C isotherms;
- a decrease in the size of the area $\leq 17^{\circ}\text{C}$; and
- a southward shift of the northern boundary of the cold water area.

For purposes of ecosystem modelling, the regressions presented in Table 2 can be used to assess the variation of the habitat size of anchoveta and its main predators.

Muck et al. (1987) put forward the hypothesis that changes in the spatial parameters area (alongshore, extent, onshore-offshore distance) of the cold and warm water habitats off Peru control - or at least influence - the migration and concentration pattern of anchoveta and of mackerel and horse mackerel, resulting, e.g., in changes of anchoveta vulnerability to predation, to egg and larval cannibalism and to the fishery.

This hypothesis is supported by Ware and Tsukayama (1981) who noted that anchoveta concentration increases with positive temperature anomalies. A direct relationship between water temperature and anchoveta density can also be shown to exist (Fig. 4).

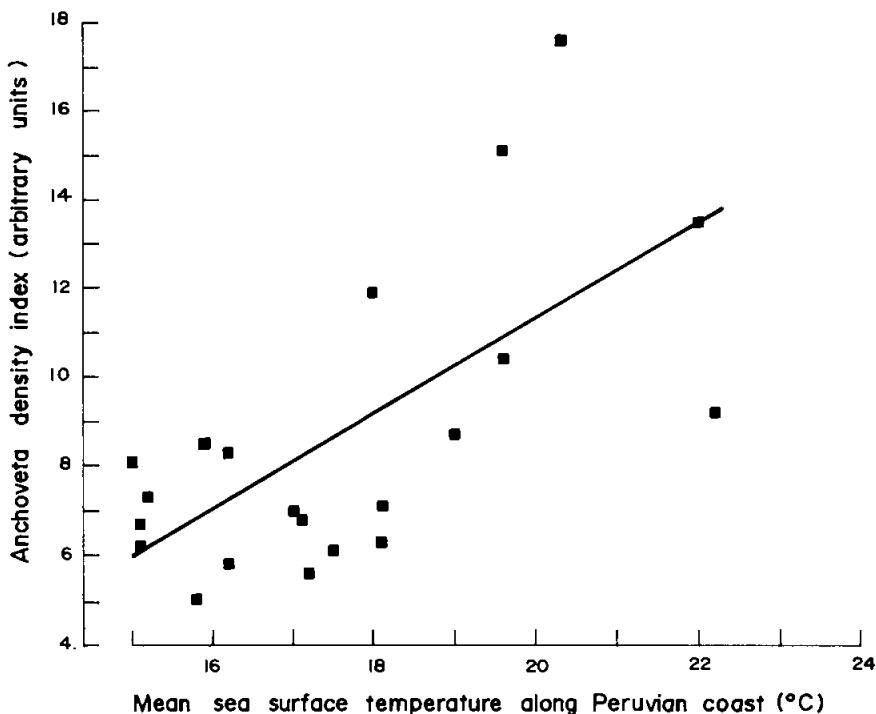

Fig. 4. Relationship between anchoveta density and SST off Peru (based on data in Table 3).
Fig. 4. Relación entre la densidad de la anchoveta y TSM frente al Perú (basados en datos de tabla 3).

Changes in anchoveta density imply changes of anchoveta biomass and/or of the size of anchoveta distribution area. Analysis of the data in Table 3 shows that the anchoveta distribution area is significantly correlated ($P < 0.05$; $r = 0.42$) with the area of water $\leq 17^{\circ}\text{C}$, and with anchoveta biomass (B) as well ($P < 0.005$; $r = 0.62$).

Table 2. Statistics of linear relationships between sea surface temperature off Peru and some dependent variables (see also Fig. 2).^a
Tabla 2. Estadísticas de relaciones lineales entre la temperatura superficial del mar frente al Perú y algunas variables dependientes (ver también Fig. 2).

| Plot in Fig. 1 | Dependent variables (units) | Intercept (a) | Slope (b) | S.E. of b | Correlation coefficient (r) ^c | Degrees of freedom |
|----------------|---|---------------|-----------|-----------|--|--------------------|
| A | Sea area (10^3 Nm^2) ≤17°C | 420 | -21.4 | 4.37 | 0.71 | 26 |
| B | Offshore extent of area ≤17°C (Nm) | 264 | -12.5 | 3.06 | 0.63 | 27 |
| C | Alongshore extent of area ≤17°C (Nm) | 4,440 | -226 | 33.5 | 0.81 | 26 |
| D | Northern limit of area ≤17°C (° South) | -46 | 3.03 | 0.42 | 0.85 | 23 |
| E | Offshore extent of area ≤20°C (Nm) | 220 | -8.74 | 2.22 | 0.64 | 24 |

^aBased on seasonal means for 1970 to 1985 (in Table 1).

^bHere and elsewhere, nm refers to nautical mile, i.e., 1,852 km.

^cAll correlation coefficients are significant ($P < 0.05$).

Table 3. Data for establishing relationships between sea surface temperature off Peru and the distribution area and density of anchoveta.
Tabla 3. Datos para establecer relaciones entre la temperatura superficial del mar frente al Perú y el área de distribución y densidad de la anchoveta.

^aFrom Pauly and Tsukayama (1987b), and pertaining to the Peruvian coast from 4° to 14°S.

^bFrom Fig. 2A and corresponding regressions in Table 2; predicted areas < 0 were set = 0; 1 $\text{Nm}^2 = 3.43 \text{ km}^2$.

^cFrom Zuta et al. (1983).

^dFrom Pauly et al. (1987).

However, predictions can be markedly improved by combining three variables into a log-linear model, e.g., into

$$\log_{10}A = 0.8177 + 0.3492 \log_{10}B + 0.1396 \log_{10}(C + 1) \quad \dots 1)$$

where A is the anchoveta distribution area (in 10^3Nm^2) off Peru,
 B the biomass of anchoveta (in $\text{t} \cdot 10^6$)
 and C the area of water $\leq 17^\circ\text{C}$ (in 10^3Nm^2)

This model, based on the data of Table 3, has a multiple correlation coefficient $R = 0.794$ and explains 62.1% of the variance in the data set. Both of its partial slope are significantly different from zero ($P < 0.01$; d.f. 23).

As an alternative, one can replace the variable (C) in equation (1) by the SST values from which the C-values were computed (see Table 3) and this yields

$$\log_{10}A = 3.23 + 0.3483 \log_{10}B - 1.797 \log_{10} \text{SST} \quad \dots 2)$$

where $R = 0.780$ ($R^2 = 0.608$) and where both slopes are significant ($P < 0.01$), and which applies, as did equation (2), to the stretch of the Peruvian coast between 4° and 14°S .

The good fit of these models to the available data validates the concept of a Main Anchoveta Area (MAR), first proposed and used as a constant by Muck and Sánchez (1987), and now shown to be an SST-dependent variable.

The interrelationships between SST, anchoveta concentration and the spatial characteristics of its habitat imply an increase of anchoveta mortality by predators and the fishery when the distribution area of mackerel and horse mackerel overlaps with that of anchoveta (Muck and Sanchez 1987), especially during El Niño events.

This is also a time when the anchoveta schools are concentrated close to the coast and hence highly vulnerable to the purse seiner fleet. Valdivia (1978) reports that during the El Niño event of 1971-1972 anchoveta were so concentrated that 170,000 t of them were caught in a single day, in March 1972 (see also Csirke, this vol.).

When an El Niño event, however, becomes so strong that the cold waters completely disappear (as is nearly the case in Fig. 1 lower panel), anchoveta vulnerability to the fishery fleet abruptly drops to near-zero values because of the vertical displacement of the pelagic schools out of the purse seiners' range. This has been observed during the last very strong El Niño event of 1982-1983 and is also reported in Muck and Vilchez (1986).

Changes in the area of the cold water habitat also influence anchoveta recruitment. Csirke (1980), who added to the standard stock/recruitment model of Ricker (1954) an "anchoveta concentration index", found that an increase in the concentration of the parent stock during spawning resulted in less recruits in the next year which suggests a density-dependent egg and larvae cannibalism. Ware and Tsukayama (1981), who used a bioenergetics model of anchoveta recruitment suggested that increases of anchoveta concentration during spawning cause reduced egg production (via crowding effects) and/or lead to food competition between the spawning stock and its progeny, which may result in reduced larval survival.

Thus, the dynamics of SST-related parameters such as the area of water $\leq 17^\circ\text{C}$, and the onshore and alongshore extent of the 17°C and 20° isotherms for which several expressions are given in the present contribution, appear to be of crucial importance for anchoveta population growth and should be taken in account when modelling the Peruvian upwelling ecosystem.

Abstract

The hypothesis that the poleward propagation of El Niño events along the coast of South America is due to Kelvin waves lacks stringent confirmation by observation. Observations are discussed which refute the Kelvin wave model. An alternative concept of poleward propagating shock waves is proposed. Some of its basic features and advantages are discussed.

Resumen

La hipótesis que la propagación de los fenómenos de El Niño a lo largo de la costa de América del Sur es debido a las "ondas de Kelvin" adolece de una confirmación concluyente por medio de mediciones. Las observaciones que refutan el modelo de "ondas de Kelvin" están discutidas. Un concepto alternativo de propagación de "onda shock" es propuesto. Se discute algunas de sus características básicas y ventajas.

Introduction

Southern oscillation events are linked to equatorial Kelvin waves crossing the Pacific towards South America (see, e.g., Cane 1983; Käse 1985). The equatorial current system creates Kelvin waves by shear instability (Philander et al. 1985). The South American coast acts as wave guide for Kelvin waves of about 5 to 10 days period, more than 1,000 km wave length and 2.5 ms^{-1} phase velocity (Romea and Smith 1983). Equatorial Kelvin waves, incident on the South American coast, give rise to coastal Kelvin waves propagating poleward (Anderson and Rowlands 1976; Brink et al. 1983).

El Niño southern oscillation events propagate poleward along the coasts of Ecuador and Peru with phase velocities similar to those of coastal Kelvin waves (Smith 1983). The problem to be considered here is: are the dynamics of the southward propagating El Niño events those of a Kelvin wave as suggested by Cane (1983)? The Kelvin wave hypothesis seems to be acceptable because it provides both a reasonable estimate of the mean speed of alongshore propagation of the El Niño events and also provides a triggering mechanism. However, observations and theoretical considerations can be assembled which, together, indicate that the Kelvin wave hypothesis may be too restrictive and should be replaced by a more general concept.

Theoretical Considerations

A Kelvin wave has several main features which do not depend on the technique used to derive the solutions from the governing equations. The current amplitude u decreases with increasing offshore distance y (x is the alongshore distance, t the time). If H is the vertical displacement of the isotherms, then the proportionality

$$u(x, y, t) \simeq \partial/\partial y H(x, y, t) \quad \dots 1)$$

holds. The alongshore propagation of the wave is like a gravity wave, thus there is a proportionality such as

$$\partial/\partial t u(x, y, t) \simeq \partial/\partial x H(x, y, t) \quad \dots 2)$$

The phase speed of the Kelvin wave is nondispersive. Thus its propagation speed is independent of wave frequency. Therefore, a general-wave like solution of (1) and (2) may be obtained by:

$$\begin{aligned} u(x, y, t) &= U(y) * F(x - ct) \\ H(x, y, t) &= H(y) * F(x - ct), \end{aligned} \quad \dots 3)$$

where c is the phase speed and $x - ct$ the phase (abbreviated below as s). From (3) and (2) follow the proportionalities:

$$\begin{aligned} -c * U(y) * \partial/\partial s F(s) &\simeq H(y) * \partial/\partial s F(s) \\ \text{or } c &\simeq H(y)/U(y) \end{aligned} \quad \dots 4)$$

$H(y)$ and $U(y)$ differ by a constant factor, and, using (1), are exponentially decreasing with increasing offshore distance.

$$\begin{aligned} U(y) &\simeq \exp(-y/1) \\ H(y) &\simeq \exp(-y/1) \end{aligned} \quad \dots 5)$$

The constant 1 can be identified as the Rossby radius of deformation (Krauss 1973).

Data off Peru to test these main characteristics of currents and isopycnal depths (equations (1), (2), or derived proportionalities) are, to the authors' knowledge, not yet available. Thus, the Kelvin wave character of the motion is still hypothetical. However, the data from which Brainard and McLain (1987) derived the monthly mean depths of the 14-degree isotherm may be rearranged to test whether the proportionality of equation (6), which combines equation (1) and (2), holds.

$$\partial/\partial x H(x, y, t) \simeq \partial/\partial t \partial/\partial y H(x, y, t) \quad \dots 6)$$

If this proportionality holds and if likewise the nondispersive character of the phase speed is shown, then the linear Kelvin wave character of the El Niño events along the coasts of Peru could be demonstrated.

The linearity of the motion is implicit due to the form of equation (3). The linearity of the wave may be questioned. The poleward increasing influence of the earth rotation causes an increasing trapping of the wave energy against the shoreline. The Rossby radius decreases by a factor of two from either 2.5°S to 5°S, or 5°S to 10°S, or 10°S to 20°S. Therefore, a longshore gradient of the mean current amplitude will build up if not balanced by, e.g., frictional dissipation. Otherwise the motions will be subject to nonlinear accelerations.

Observational Considerations

Observations made during El Niño events are presented below which do not agree with the notion of one long, linear Kelvin wave propagating along the coast.

- a) Posner (1957) reported that the 1953 El Niño advanced twice and retreated twice during the observation period from 10 March to 21 May 1953. Wooster and Guillén (1974) reported for the 1972 El Niño event "no systematic progression of anomalous conditions southward along the coast"
- b) Smith (1983) described the 1982 El Niño event linked to a rapid, stepwise increase of the currents (Fig. 1) in 100 m depth: "the alongshore current, averaged over 1, 8, and 64 days before 7 October, was poleward at 18.9, 18.0, and 4.2 cm/s, respectively. Mean alongshore current abruptly accelerated to 35.8 cm/s poleward on 7 October, and current averaged over following 8 and 64 days remained poleward at 30.1 and 25.3 cm/s." Temperature (see his Fig. 2) increased steplike, first in small (from early October to mid-November), then in large steps. Furthermore, strong temperature changes were found in different depths (Knoll et al. 1987: p. 33 - end of March 1983, p. 113 - October 1982, p. 117 - April and May 1983) which neither occurred in phase nor had smooth forefronts. Both features are not consistent with a Kelvin wave dynamic.

The sea level changes at Santa Cruz and Callao in 1982 and 1983 were fluctuating stepwise, as shown by Cane (1983). Single steps may be smoothed to give the impression of a monotone mean rise like Cane's figure of the canonical El Niño. However, an approximation by a stepping function would probably be more appropriate (Fig. 2).

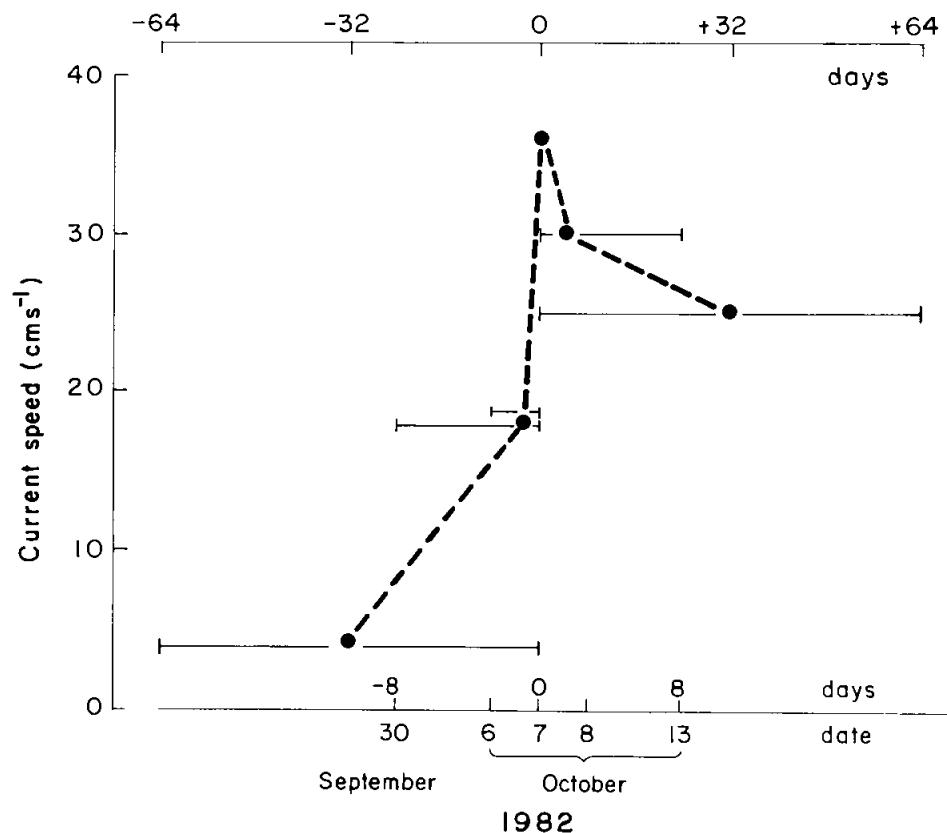

Fig. 1. Averaged current speeds observed at 10°S in 100 m depth (bottom depth 150 m) by Smith (1983) around 7 October 1982. Horizontal bars give the time intervals for which the mean values (vertical axis) have been calculated. Note the uneven scaling of the time axis. The broken line indicates how the mean currents would change for an evenly scaled time axis (upper line).

Fig. 1. Velocidades de corriente promediadas a 10°S y 100 m de profundidad (profundidad del fondo 150 m) de Smith (1983) alrededor del 7 de Octubre 1982. Las barras horizontales dan intervalos de tiempo del cálculo medio de las corrientes (línea vertical). Notar la desigualdad regular de la línea del tiempo. La línea puntillada indica como las corrientes medias podrían cambiar para una escala de tiempo equidistante (línea superior).

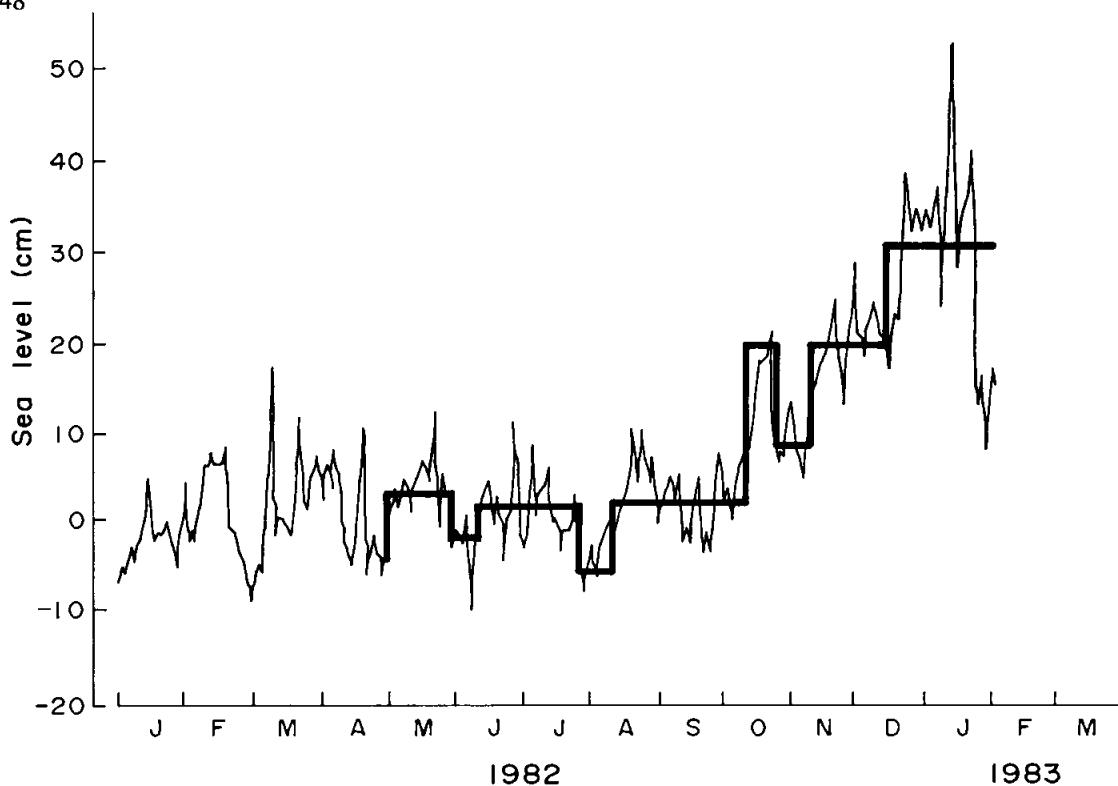

Fig. 2. Sea level changes at Callao (redrawn from Cane 1983). Superimposed is a suggestive stepwise approximation, contrasting with the common interpretation of smooth changes.

Fig. 2. Variaciones del nivel del mar en Callao (redibujado de Cane, 1983). La línea superimpuesta es una sugerida aproximación de pasos en contraste con la interpretación común de cambios suavizados.

Discussion

The observations presented above imply a motion expressed by nonlinear, steplike changes and intermittence. These are features which do not match simple wave dynamics. Furthermore, a stringent confirmation of the Kelvin wave hypotheses by observations is lacking. Thus, it seems reasonable to suggest that the dynamic features of the El Niño events off Peru should be reanalyzed. Of special importance is the question whether the poleward propagating motion is a single or a composed signal and how linear the event is. The latter characteristic would determine to which degree locally and remotely forced motions may interact, e.g., exchange energy.

A possible dynamic concept, including the Kelvin wave concept to a certain degree, is implied in the nonlinear model developed by Nof (1987a, 1987b) and applied to various hydrodynamic problems (Nof 1987a, 1987b; Nof and Van Gorder 1987), and which implies the possibility of boundary currents supporting propagating, frontlike disturbances, dissipating shock waves, e.g., steplike increases of the surface layer depth or the current speed.

Results obtained for the Mediterranean outflow (Nof 1987a, 1987b) may apply, after proper scaling, to the Peruvian Undercurrent. However, only the concept of shock waves itself needs to be discussed here. The model predicts that these shock waves will move more rapidly than a Kelvin wave downstream from the front. An upstream Kelvin wave will catch up with the front. Thus, the front does not disintegrate in alongshore direction and will be maintained against frictional losses and offshore oriented Rossby wave dispersion by energy radiating from an upstream source. The alongshore penetration length of single shock wave will depend on the relative strength of the shock itself and on dissipation or dispersion. The generation of poleward propagating shock waves may be due to the observed pulsation of the Equatorial Current System (Lukas 1986). El Niño signals may be caused by these pulses especially if combined with the downwelling stroke of the isopycnals occurring east of the Galapagos Islands in early autumn and spring (Lukas 1986).

The sequence of shock waves, eventually followed up by Kelvin waves, may serve as a conceptual model. Each El Niño event can be assumed to be built by a particular sequence of shock waves. This would explain both the intermittence and the characteristics of particular El Niño events. Furthermore, the shock wave concept offers the possibility to analyze the observed nonlinear kinematic features. The nonlinear dynamics of the concept suggest that a free superposition of different motions may not be possible. Thus, a particular feedback between locally forced motions and remotely triggered waves may be possible.

Abstract

A model was used to estimate the potential primary production of the Peruvian upwelling ecosystem from 1953 to 1984. A monthly time series of thermocline depth was converted to nitrate concentration at 60 meters using an empirical relationship between the depth of the thermocline and the concentration of nitrate at 60 m. A time series of new production was created using the time series of nitrate concentration at 60 m and a monthly time series of upwelling rates coupled with a Redfield ratio conversion of nitrogen to carbon. The new production time series was converted to primary production using the "f" ratio, 0.75 for the coast of Peru. The estimates of primary production were compared to values obtained using C-14 uptake and the results were similar. The interannual variability in new production generally followed the expected pattern, with lower new production during El Niño and higher new production during cool years. The level of new primary production of the Peruvian upwelling ecosystem is substantially higher than previous estimates and has remained relatively constant through time. The overall results are encouraging but the model still requires adjustment for the area over which the new production is realized.

Resumen

Se usó un modelo para estimar la producción primaria potencial del ecosistema de afloramiento junto a la costa del Perú, entre 1953 y 1984. La serie de tiempo mensual de la profundidad de la termoclina fué convertida a concentración de nitrato a 60 metros usando una relación empírica entre la profundidad de la termoclina y la concentración de nitrato a 60 metros. Se calculó una serie de tiempo de nueva producción primaria usando la serie de tiempo de nitrato a 60 metros y una serie de tiempo de afloramiento, junto con una conversión Redfield de nitrógeno a carbono. La nueva producción primaria se convirtió a producción primaria total, usando un valor de "f" de 0.75. Se compararon los valores estimados usando esta técnica con valores obtenidos usando la incorporación de C-14 por fitoplancton y los resultados fueron similares. La variabilidad interanual de la nueva producción primaria siguió generalmente el patrón esperado, con producción más baja durante El Niño y más alta durante los años fríos. La magnitud de la producción primaria del ecosistema de afloramiento junto a la costa del Perú es sustancialmente más elevada que los estimados previos y se ha mantenido relativamente uniforme con el tiempo. Los resultados preliminares son alentadores, pero el modelo requiere mayor atención a los aspectos físicos que modulan el afloramiento y el área que es afectada por este fenómeno.

Introduction

The southeastern tropical Pacific produces a significant proportion of the global pelagic fish harvest (FAO 1983). The richness of living resources is a consequence of high levels of primary production which result from abundant concentrations of inorganic plant nutrients at the surface in a tropical setting (Ryther 1969; Cushing 1971). Primary production in the ocean, however, is highly variable in space and time (Steele 1977). On the other hand, temporal and spatial observations of primary productivity in the ocean are relatively few. Because of the high

*Present address: Monterey Bay Aquarium Research Institute, 160 Central Ave., Pacific Grove, California 93950, USA.

variability in primary productivity in space and time and the few direct observations of primary productivity, it is important to develop indirect methods of estimating primary productivity which integrate over space and time. One such indirect approach involves using upwelling models (Chavez and Barber 1987).

New primary production is primarily supported by upwelling which provides the euphotic zone with nitrate from below the thermocline (Dugdale and Goering 1967). The potential new production of a region is therefore determined by the amount of nitrate upwelled into the euphotic zone. An estimate of the potential new production can be made by estimating the nitrate concentration of the upwelled water and estimating the volume of water upwelled. Wyrtki (1963) estimated the volume of water upwelled for a region in the southeastern tropical Pacific from 6°S to 24°S to be $1.0 \times 10^{14} \text{ m}^3/\text{year}$. Using the Wyrtki (1963) estimate of the volume of water upwelled and assuming a nitrate concentration of $25 \mu\text{g-at./l}$ in the source water, a potential new production of $2.0 \times 10^{14} \text{ gC/year}$ was estimated (Chavez and Barber 1987). The calculation assumes all upwelled nitrate is taken up by phytoplankton and uses a Redfield ratio conversion of nitrogen to carbon.

As part of a multidisciplinary effort designed to study the variability of living resources along the coast of Peru, long time series of monthly averages of physical and biological parameters have been compiled (Pauly and Tsukayama 1987). The spatial domain over which the multidisciplinary effort concentrates is the region along the coast of Peru from 4°S to 14°S. The temporal domain is from 1953 to 1982 and in some cases until 1985. Following a logic similar to that outlined below for the Wyrtki (1963) estimate of upwelling (Fig. 1) we have taken the upwelling time series compiled by Bakun (1987)^a and the thermocline depth time series compiled by Brainard and McLain (1987) as part of the multidisciplinary study and converted them to a time series of new primary production (*sensu* Dugdale and Goering 1967).

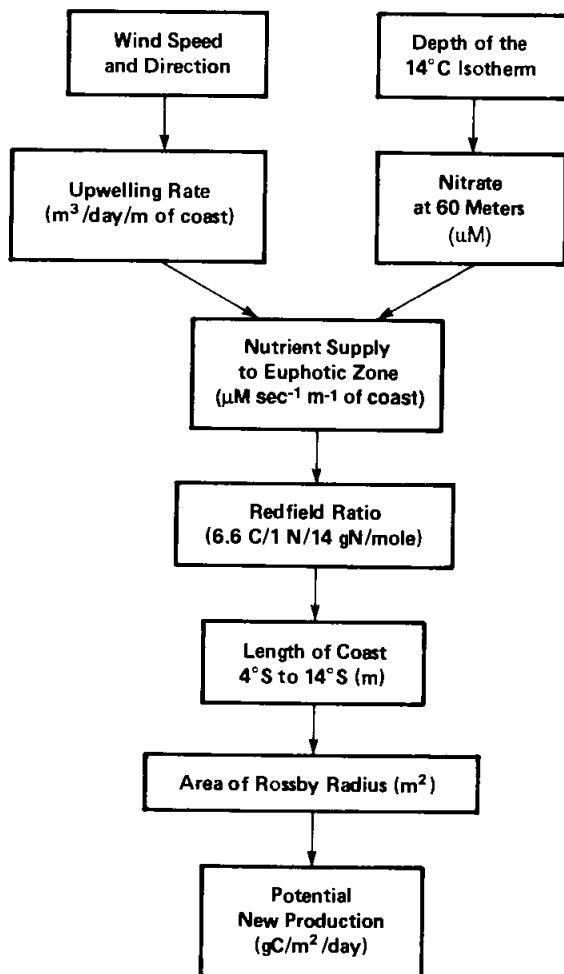

Fig. 1. Flow chart showing the logic involved in converting wind speed and direction and the depth of the 14°C isotherm to potential new production ($\mu\text{M} = \mu\text{g - at./l}$).

Fig. 1. Carta de flujo mostrando la lógica utilizada en convertir la velocidad y dirección del viento y la profundidad de la isoterma de 14°C, a nueva producción potencial ($\mu\text{M} = \mu\text{g - at./l}$).

^aEditors' note: The use of Bakun's (1987) series implies a slight bias, not likely to affect final results (see Bakun and Mendelsohn, this vol.).

Materials and Methods

Barber and Smith (1981) have estimated that water upwelled along the coast of Peru comes from between 50 and 75 m, therefore the nitrate concentration at 60 m is a good proxy for the nitrate concentration of the upwelled water. During the period 1982-1984 the nitrate concentration at 60 m at Paita, Peru (5°S) was found to be a function of sea level and thermocline depth (Fig. 2). Long time series of nutrient concentrations for the coast of Peru do not exist; however, a long monthly time series of thermocline depth (the depth of the 14°C isotherm) has been compiled by Brainard and McLain (1987) from the US Navy Fleet Numerical Oceanography Center (FNOC) Master Oceanographic Observations Data Set (MOODS). The concentration of nitrate in the upwelled source water can be estimated by finding a relationship between the depth of the 14° isotherm (a proxy for the depth of the thermocline) and the nitrate concentration at 60 m. Using data collected on cruises during November and December 1981 and February, November, and December 1983, a significant relationship between the depth of

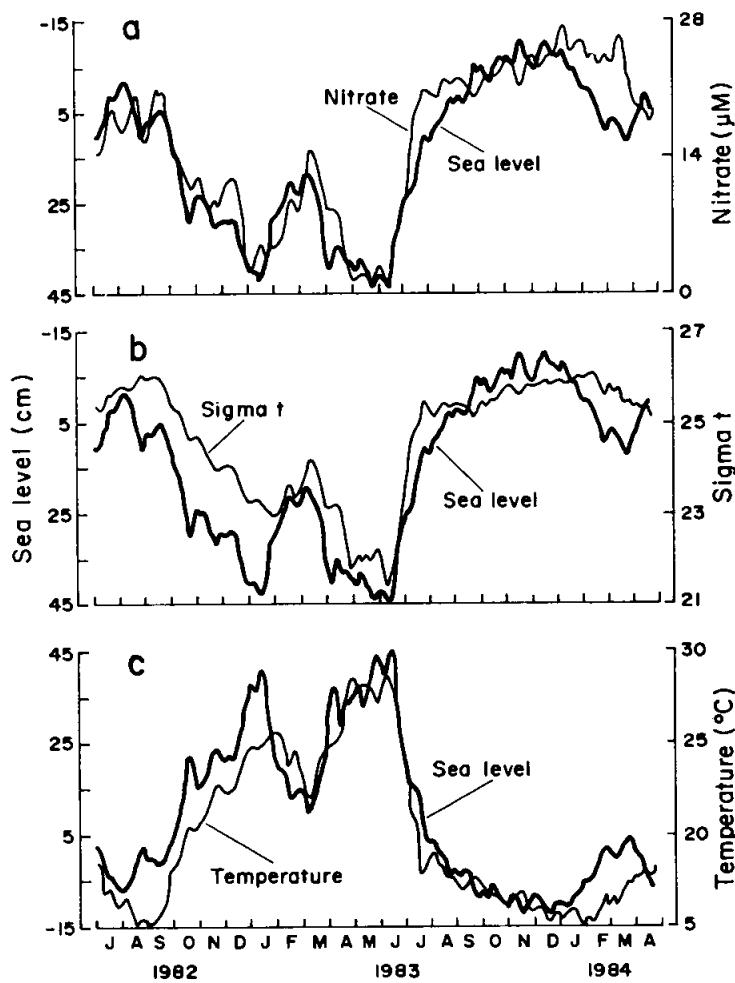

Fig. 2. Relationship between sea level measured at a pier in Paita, Peru ($5^{\circ}03'\text{S}$, $81^{\circ}07'\text{W}$) and (a) nitrate at 60 m, (b) sigma-t at 60 m, and (c) temperature at 60 m measured at an offshore station ($5^{\circ}05'\text{S}$, $81^{\circ}15'\text{W}$) during 1982, 1983, and 1984. Sea level was measured continuously by David Enfield of Oregon State University. Daily values were smoothed with a normal filter (Holloway 1958) to suppress frequencies of less than one week. The nitrate, sigma-t, and temperature were measured three times a week, interpolated to daily values (Stineman 1980) and smoothed as the sea level.

Fig. 2. Relación entre el nivel de mar medido en el muelle de Paita, Perú ($5^{\circ}03'\text{S}$, $81^{\circ}07'\text{W}$) y (a) nitrato a 60 m; (b) sigma-t a 60 m y (c) temperatura a 60 m medida en una estación fuera de la costa ($5^{\circ}05'\text{S}$, $81^{\circ}15'\text{W}$) durante 1982, 1983 y 1984. El nivel de mar fue medido continuamente por David Enfield de la Universidad del Estado de Oregon. Los valores diarios fueron suavizados mediante un filtro normal (Holloway 1958) para suprimir frecuencias de menos de una semana. El nitrato, sigma-t, y la temperatura se midieron tres veces por semana, se interpolaron a valores diarios (Stineman 1980) y se suavizaron como los del nivel de mar.

the 14° isotherm and the nitrate concentration at 60 m was found. The regression equation of nitrate on the depth of the 14° isotherm was: nitrate = $44.15 - (0.20 \times \text{depth of the } 14^\circ \text{ isotherm})$ with a regression coefficient of -0.82 and a slope which is significantly different from zero at $P < 0.01$. Using this equation, the long monthly time series of the mean depth of the 14° isotherm created by Brainard and McLain (1987) was converted to concentrations of nitrate at 60 m.

There are several factors which have not been considered in the present analysis and could potentially bias the calculations. No correction is applied for denitrification. Denitrification has a similar effect on new primary production as El Niño: it reduces the concentration of nitrate in the upwelled water. Stations which exhibited strong denitrification were excluded from the regression between nitrate at 60 m and the depth of the 14°C isotherm. In addition shortly after the 1982-1983 El Niño waters of very high salinity and abnormal nitrate to temperature relationship (i.e., low temperatures and low nitrate concentration) remained close to the coast. These stations also were not considered in the present analysis.

The second parameter needed to estimate potential new production is the amount of water upwelled. A long time series (1953-1984) of monthly upwelling rates has been constructed by Bakun (1987). The upwelling rates are calculated from maritime measurements of wind speed and direction (Bakun et al. 1974) and the units are $\text{m}^3/\text{sec}/\text{m}$ of coast. To see how the volume of upwelling calculated from the upwelling rate compared to other estimates of the volume of water upwelled along the coast of Peru (Wyrtki 1963) we estimated the mean volume of water upwelled for the stretch of coast from 4° to 14°S using the upwelling rates. From the upwelling time series we calculated a mean upwelling rate of $2.17 \text{ m}^3/\text{sec}/\text{m}$ of coast. The calculated mean volume of water upwelled for the length of the coast (4°S to 14°S) for the period from 1953 to 1984 is $7.6 \times 10^{13} \text{ m}^3/\text{year}$. The volume calculated here is very similar to that estimated by Wyrtki (1963) using geostrophy, supporting this method of calculation of upwelling volume. A potential bias of using upwelling models which depend solely on the wind (Bakun 1987) is that there are times when upwelling favorable winds along the coast of Peru produce no upwelling (Huyer et al. 1987). This happens at times during El Niño and perhaps during summer months.

Following the logic outlined in Fig. 1, the long time series of nitrate concentration and upwelling rate coupled with a Redfield ratio conversion of nitrogen to carbon were used to construct a long time series of potential new production. Since the theoretical offshore dimension of coastal upwelling is the Rossby radius of deformation (Yoshida 1967) an estimate of the area affected by coastal upwelling between 4°S and 14°S can be made. Taking the total productivity of the length of the coastline and dividing by the area we converted the production into daily or yearly rates per m^2 so that comparisons to productivities measured using other techniques could be made (Table 1).

The thermocline depth time series was incomplete so that smoothing and time series analysis could not be easily performed. In order to fill in the gaps we searched for relationships between thermocline depth and other physical variables. A multiple regression using the mean Peru SST and an index of the Southern Oscillation (Brainard and McLain 1987) gave a regression coefficient of 0.63 which was significant ($P < 0.001$). The missing thermocline depths were found using the multiple regression equation. With the complete series we were able to smooth the data in order to suppress the annual cycle, using a 13-month running mean.

In order to investigate the higher frequency variability, time series analysis was performed on the long monthly time series. In order to determine seasonal cycles in the time series the long-term means of individual months were calculated. Trend analysis was also performed on the time series data in order to investigate long-term trends of the data. Spectral analysis was used to identify the important frequencies of the time series.

Results

The grand mean concentration of nitrate at 60 m for the entire time series is $22.21 \mu\text{M}$. This together with the mean upwelling rate converts to a mean potential new production of $844 \text{ gC/m}^2/\text{year}$. Chavez and Barber (1987) have estimated a mean total production of $834 \text{ gC/m}^2/\text{year}$ for 1983, 1984, and 1985 using C-14 carbon uptake experiments. Others (Walsh 1975, 1981; Cowles et. al. 1977; Shushkina et. al. 1978; Barber and Smith 1981; Chavez and

Barber 1985; and Barber et. al. 1986) have also estimated total primary production for the Peruvian upwelling system. In order to compare the new production estimates to total production estimates it is necessary to convert new production to total production. Although new production is a fraction of total production, for the coast of Peru this fraction is high and has been estimated as 0.75 (Dugdale 1985). Using Dugdale's (1985) estimate of the "f" factor (the ratio of new to total production) for the Peruvian upwelling system, the potential new production was converted to total production. Comparison of estimates made in this paper to estimates made using C-14 uptake (Table 1) shows the estimates made using the physical data and those from C-14 measurements are very similar. There is then good agreement between the estimates from the physical data sets and those from C-14 uptake experiments.

Table 1. Comparison of published estimates of production for the Peruvian upwelling system to the estimates made from our method of calculation. The potential new production was converted to total production using a ratio of new to total production (the "f" factor) of 0.75 (Dugdale 1985).

Interannual Variability

The time series of depth of the 14° isotherm shows that the isotherm is deepest during periods of El Niño Southern Oscillation (see Fig. 3 and Brainard and McLain 1987). From 1956 through 1961 the depth of the 14° isotherm remained relatively constant at about 120 m. The depth of the 14° isotherm during El Niño ranged from 120 m in 1957 to 160 m in 1983. The average depth of the 14° isotherm during non-El Niño years is about 100 m.

The nitrate concentration at 60 m, a mirror image of the depth of the 14° C isotherm, has minima during the El Niño years (Fig. 4). The lowest value occurred in 1983 where the concentration of nitrate was about 13 µM. The highest concentration of nitrate occurred in 1971 at 27 µM. Just like the depth of the 14° isotherm, the nitrate concentration data had a relatively constant value of about 21 µM between 1956 and 1961.

The time series of the rate of upwelling showed peaks during El Niño years (Fig. 5) supporting the observations of Enfield (1981) who first suggested that during El Niño the coastal winds which drive upwelling intensify. During normal time periods, the average upwelling rate is about 2.0 m³/sec/m of coast. The lowest rate being about 1.5 m³/sec/m of coast occurred in 1959 and the strongest rate of 3 m³/sec/m of coast occurred in 1983. The range of upwelling rate during El Niño years is from 2 to 3 m³/sec/m of coast occurring in 1969 and 1983, respectively.

The time series of new production (Fig. 6) shows that production is lower than the mean during El Niño years except during part of 1957 when the production was about 2.6 gC/m²/day. During the other El Niño years, the production ranged from 1.7 gC/m²/day in 1983 to about 2.2

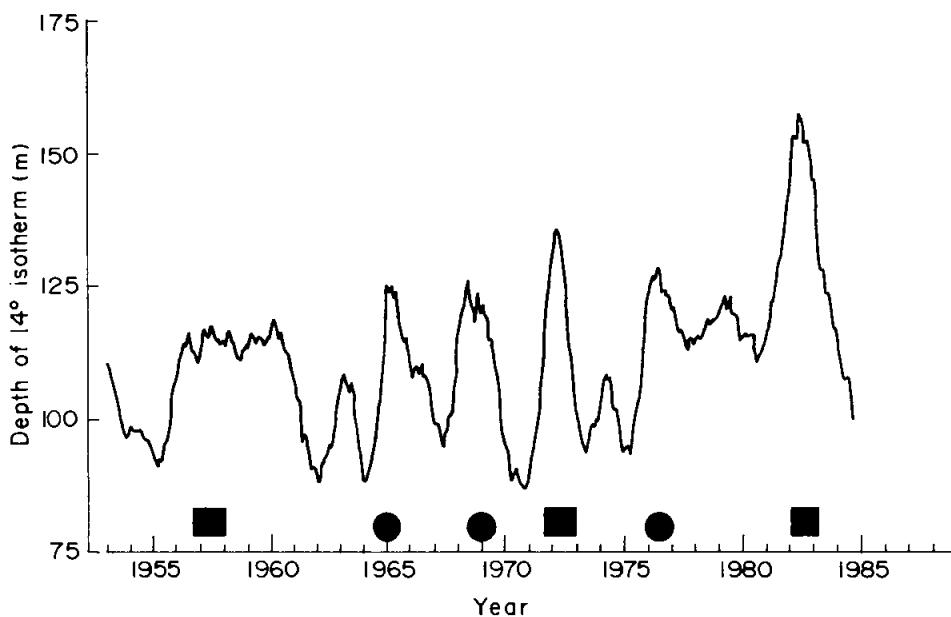

Fig. 3. Time series of the depth of the 14° isotherm (m). The time series was smoothed using a 13-month running mean and the tickmarks on the x-axis represent the middle of the year. The highest peaks on the graph represent the deepest depths; these occur during El Niño years. The 14°C isotherm is from Brainard and McLain (1987). The periods of El Niño are represented by darkened squares for strong and darkened circles for weak El Niño events.

Fig. 3. Serie de tiempo de la profundidad (m) de la isoterma de 14°C. La serie de tiempo fué suavizada usando promedios móviles de trece meses y las marcas en el eje horizontal representan la mitad del año. Los picos más altos en el grafico representan las mayores profundidades; estas ocurren durante los años El Niño. La isoterma de 14°C es de Brainard and McLain (1987). Los cuadrados representan los Niños fuertes y los círculos representan los Niños más débiles.

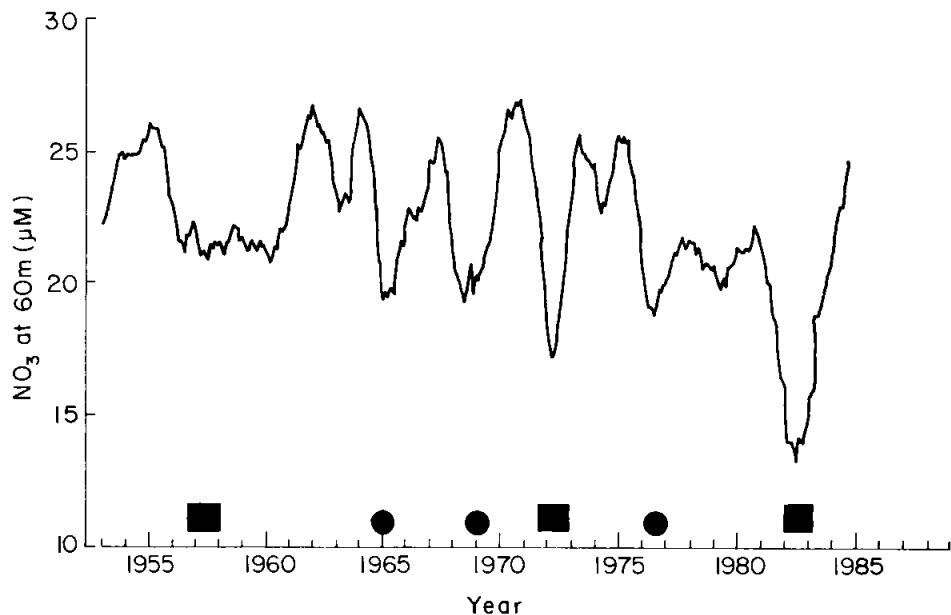

Fig. 4. Time series of the concentration of nitrate at 60 m (μM). The monthly time series was smoothed with a 13-month running mean and the tickmarks on the x-axis represent the middle of the year. This graph shows that during El Niño years the nitrate concentration at 60 m is lower than normal (or cool) years. The filled squares represent the periods of the strong El Niño events of 1957-58, 1972-73 and 1982-83 and the filled circles represent the periods of the weaker El Niño events of 1965, 1969 and 1976.

Fig. 4. Serie de tiempo de la concentración de nitrato a 60 m (μM). La serie de tiempo mensual fue suavizada usando promedios móviles de trece meses y las marcas en el eje horizontal representan la mitad del año. Esta gráfica muestra que durante los años El Niño, la concentración de nitrato a 60 m es más baja que en los años normales (o fríos). Los cuadrados representan los Niños fuertes de 1957-58, 1972-73 y 1982-83 y los círculos representan los Niños más débiles de 1965, 1969 y 1976.

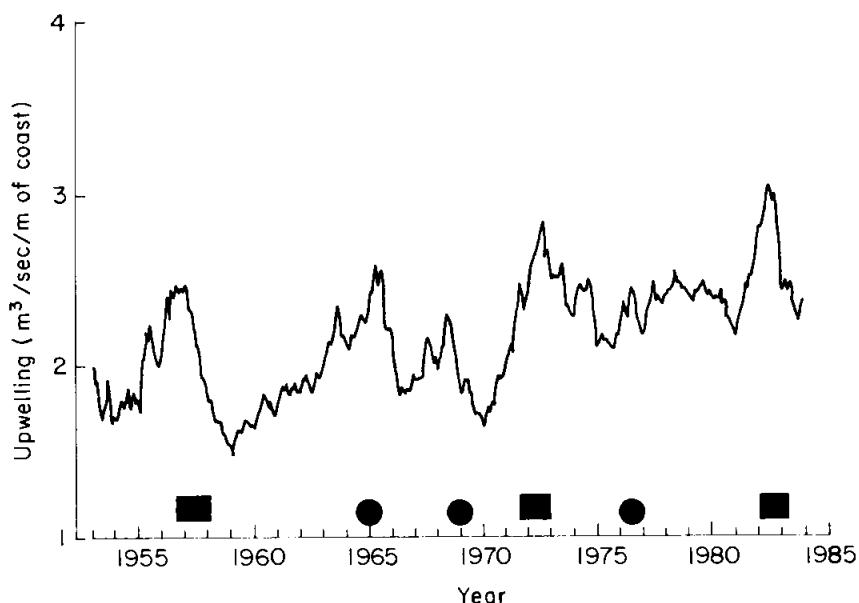

Fig. 5. Time series of upwelling rate ($m^3/\text{sec}/\text{m of coast}$). The time series was smoothed using a 13-month running mean and the x-axis tickmarks represent the middle of the year. This graph shows that the upwelling rate is stronger during El Niño events than it is during normal conditions. The upwelling rate is from Bakun (1987). The filled squares represent the periods of the strong El Niño events of 1957-58, 1972-73 and 1982-83 and the filled circles represent the periods of the weaker El Niño events of 1965, 1969 and 1976.

Fig. 5. Serie de tiempo del índice de aforamiento ($m^3/\text{seg}/\text{m de costa}$). La serie de tiempo fué suavizada usando promedios móviles de trece meses y las marcas en el eje horizontal representan la mitad del año. Esta gráfica muestra que el aforamiento es más fuerte durante los eventos El Niño que durante condiciones normales. El índice de aforamiento es de Bakun (1987). Los cuadrados representan los Niños fuertes de 1957-58, 1972-73 y 1982-83, y los círculos representan los Niños más débiles de 1965, 1969 y 1976.

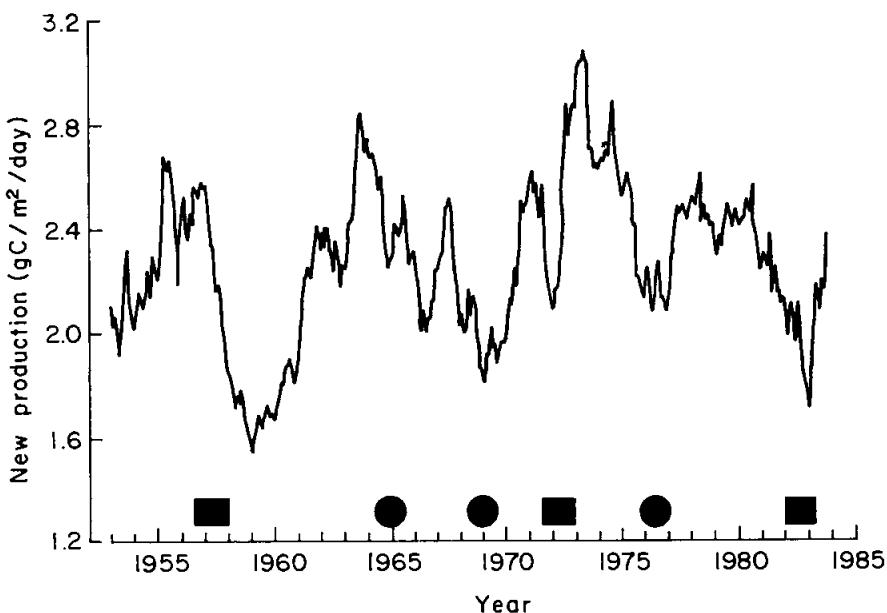

Fig. 6. Time series of new production ($\text{gC}/\text{m}^2/\text{day}$) from 1953 to 1984. The time series was smoothed using a 13-month running mean and the x-axis tickmarks represent the middle of the year. The 1957-62 negative anomaly is visible as are the valleys of low production during El Niño years except 1957. The filled squares represent the periods of the strong El Niño events of 1957-58, 1972-73 and 1982-83 and the filled circles represent the periods of the weaker El Niño events of 1965, 1969 and 1976.

Fig. 6. Serie de tiempo de nueva producción ($\text{gC}/\text{m}^2/\text{day}$) desde 1953 a 1984. La serie de tiempo fué suavizada usando promedios móviles de trece meses y las marcas en el eje horizontal representan la mitad del año. La anomalía negativa de 1957-62 es visible así como lo son los valles de baja producción durante los años El Niño excepto 1957. Los cuadrados representan los Niños fuertes de 1957-58, 1972-73 y 1982-83 y los círculos representan los Niños más débiles de 1965, 1969 y 1976.

$\text{gC/m}^2/\text{day}$ in 1965. Lowest production for the smoothed time series occurred in 1959 at $1.5 \text{ gC/m}^2/\text{day}$ and highest production occurred in 1973 at $3.1 \text{ gC/m}^2/\text{day}$. There was a strong negative anomaly in new production starting in late 1957 and ending in 1962. New production dropped to its lowest rate of $1.5 \text{ gC/m}^2/\text{day}$ in 1959. The 1957-1962 anomaly was the result of weak upwelling coupled with a relatively deep thermocline. The thermocline deepened during the 1957 El Niño and remained deep until 1962.

Seasonal Cycles

The depth of the 14° isotherm fluctuates irregularly throughout the year. In January it is at about 100 m and gets deeper in February and levels off at 120 m for March, April, and May. In June it rises to 108 m and then drops to lower than 120 m in July. By August the depth of the 14° isotherm rises to about 115 m. It levels off at 100 m for September, October, and November, then it deepens to 110 m in December (Fig. 7).

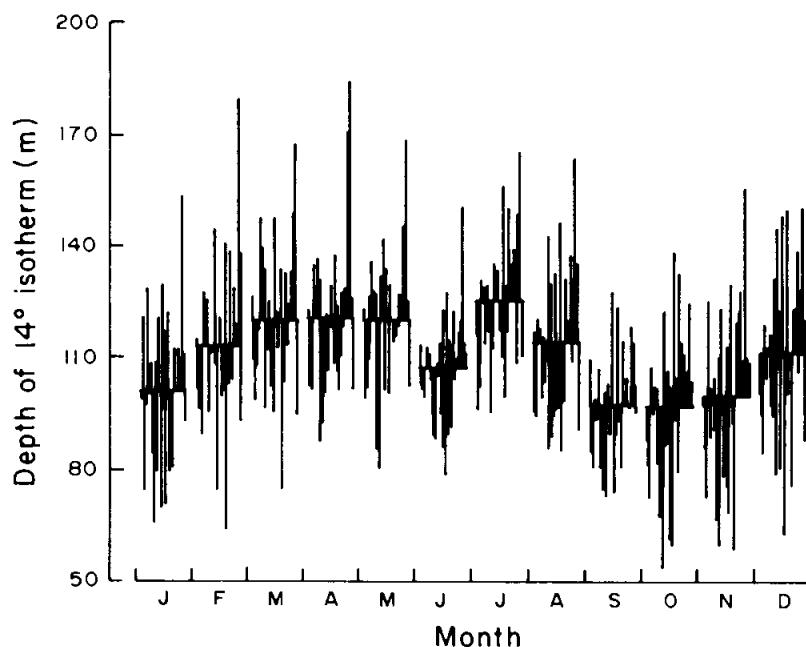

Fig. 7. Monthly plot of the depth of the 14° isotherm (m). The horizontal lines represent the average value for the month and the vertical lines represent the difference from the average to the actual value for each observation. The 14°C isotherm is from Brainard and McLain (1987).

Fig. 7. Representación mensual de la profundidad (m) de la isoterma de 14°C . Las líneas horizontales representan el valor promedio del mes y las líneas verticales representan la diferencia entre el promedio y el valor actual de cada observación. La isoterma de 14°C es de Brainard and McLain (1987).

The upwelling rate exhibits a more regular annual cycle. In January, upwelling is at its weakest, about $1.4 \text{ m}^3/\text{sec}/\text{m}$ of coast. The upwelling rate steadily increases by about 0.2 to 0.4 $\text{m}^3/\text{sec}/\text{m}$ of coast every month until July. In July, August, and September the upwelling rate is strongest at $2.8 \text{ m}^3/\text{sec}/\text{m}$ of coast. In October the rate decreases to $2.2 \text{ m}^3/\text{sec}/\text{m}$ of coast and decreases steadily until it reaches $1.6 \text{ m}^3/\text{sec}/\text{m}$ of coast in December (Fig. 8).

New production is lowest in December, January and February when it has a mean of around $1.6 \text{ gC/m}^2/\text{day}$. These months also appear to have the least interannual variability in new production. Production increases steadily until it reaches $2.8 \text{ gC/m}^2/\text{day}$ in June. In July it decreases to $2.5 \text{ gC/m}^2/\text{day}$ and is back to $2.8 \text{ gC/m}^2/\text{day}$ in August. By September, productivity reaches its highest peak of $3.3 \text{ gC/m}^2/\text{day}$. It then decreases steadily to reach $1.7 \text{ gC/m}^2/\text{day}$ in December (Fig. 9).

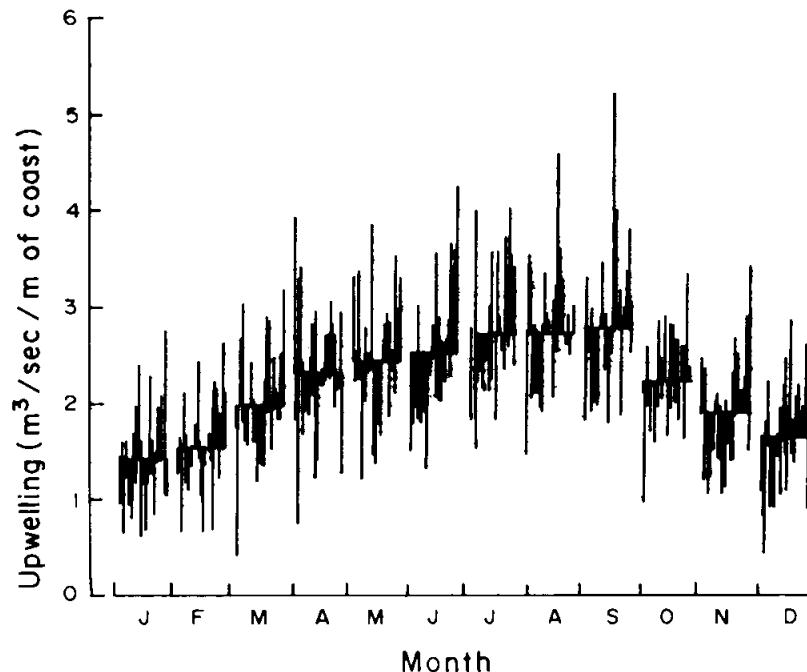

Fig. 8. Monthly plot of the upwelling rate ($m^3/sec/m$ of coast). The horizontal lines represent the average value for the month and the vertical lines represent the differences from the average to the actual value for each observation. The upwelling rate is from Bakun (1987).

Spectral Analysis

The annual cycle of the thermocline depth in the eastern tropical Pacific is apparently driven by remote annual changes in the trade winds; however it is typically believed that the important periodicities are annual and semi-annual (Myers 1979). The power spectrum for the depth of the 14° isotherm (Fig. 10) has strong variance peaks at 12 months, 4 months and 2.33 months and a surprisingly weak peak at 6 months. Nutrient observations along 85°W also suggest that the semi-annual cycle of the 14°C isotherm determined by Myers (1979) can be decomposed into three deepenings (Chavez 1987a). The variation in the depth of the thermocline along the coast of Peru may be a result of local (see below) and remote wind forcing.

The power spectrum of the upwelling rate (Fig. 11) has strong signals at 12 and 6 months. The existence of a six-month cycle in the coastal winds is probably related to the large-scale annual variations of the southeast trade wind field (Goldberg and O'Brien 1981). The power spectrum of new production is very similar to the power spectrum of the upwelling rate (Fig. 12).

Fig. 11. Análisis espectral del índice de afloramiento mostrando un fuerte ciclo de 6 meses y un ciclo de 12 meses aún más fuerte.

Trends

The trend line equation for the depth of the 14° isotherm was $101.5 + 0.05T$. The linear regression of the depth on time (T) gave a regression coefficient of $r = 0.26$; this was significant ($P < 0.01$) suggesting that over the course of the thirty-year period covered here the thermocline depth had progressively deepened. A similar trend analysis was performed on the Southern Oscillation index. The Southern Oscillation showed a significant long-term trend towards lower values. The deepening of the thermocline may be a result of the weakening of the pressure gradient which is believed responsible for maintaining the cross basin tilt in the thermocline (Wyrtki 1975).

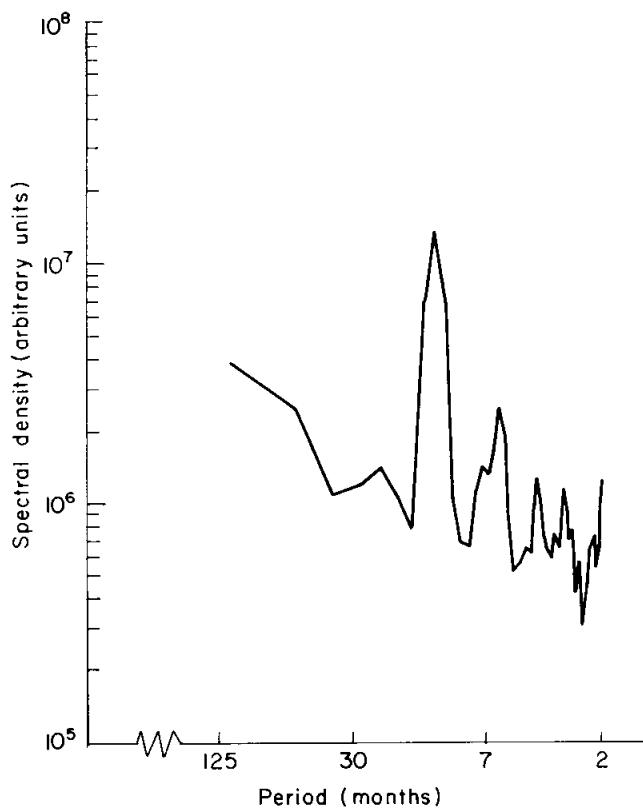

Fig. 12. Spectral analysis for new production showing a strong 6-month cycle and a stronger 12-month cycle.

Fig. 12. Análisis espectral de la nueva producción mostrando un fuerte ciclo de 6 meses y un ciclo de 12 meses aún más fuerte.

The trend line equation for the rate of upwelling was $1.80 + 1.89T$ (in months). The linear regression on time gave a regression coefficient of 0.28; this was also significant at the $P < 0.01$ level. Since upwelling along the coast of Peru is directly related to wind speed the long-term trend is for stronger winds and stronger upwelling. These findings support the observations of Whysall et al. (1987) who found a long-term trend of increasing winds in the eastern and central Pacific. Again this appears related to changes in the Southern Oscillation.

New production had a trend line equation of $2,134 + 0.71T$ (in months). The new production data were regressed on time and the resulting correlation coefficient was $r = 0.09$, which was not significant ($P < 0.05$). The trend analysis shows that during the course of thirty years the depth of the 14° isotherm and the upwelling rate increased with time, while new production remained constant over this same period. The trends in thermocline depth and upwelling rate affect new production in opposite directions. A deeper thermocline means less nitrate in the upwelled water while stronger upwelling implies that a larger volume of water is upwelled.

Discussion

Potential new production depends on the depth of the thermocline (nutricline) and on the upwelling rate. These two properties tend to be coupled temporally along the coast of Peru. They vary in such a manner that variations in the amount of nutrients supplied to the euphotic zone, and therefore potential new production, are minimized. When the thermocline is deep, such as during El Niño, upwelling is stronger and when the thermocline is shallow, during cool conditions, then upwelling is typically weaker. Enfield (1981) has determined a physical basis for these observations. When the thermocline is deep there is also warmer sea surface temperature (SST), partially a result of the deeper thermocline (see Cane 1983 for a review of the physical nature of El Niño). During periods of warmer SST (and lesser cloud cover) the land-sea temperature difference drives stronger coastal winds. Conversely periods of shallow thermocline and cool SST would be associated with weaker coastal winds.

The coastal wind scenario can be taken to the scale of the Southern Oscillation. The long-term (thirty-year) trend in the Southern Oscillation and the thermocline depth is for a weaker pressure difference and a deeper thermocline. The deeper thermocline (through increased upper ocean heat content) would result in stronger coastal winds and stronger upwelling following the logic of Enfield (1981). It is important to note that others (e.g., Rasmusson 1987) do not find a similar trend in the Southern Oscillation and have suggested that the trends in the wind data (Whysall et al. 1987) may be a result of changes in the methods of measuring winds. The trend in the depth of the thermocline, the measurement of which appears free of systematic sampling artifacts, supports the trend in the coastal winds.

The level of new production supported by upwelling along the coast of Peru has thus remained relatively constant over the thirty-year period. Periods of deeper thermocline (nutricline) are somewhat balanced by stronger upwelling. The combination of stronger winds and deeper thermocline, however, raises questions regarding the size of the area over which the new production is realized. The area calculated using the Rossby radius is the spatial domain of vertical motion or upwelling. Stronger winds and greater offshore advection should increase the area over which the new production is realized. Thus, although a similar quantity of nitrate is upwelled, the primary production driven by the upwelled nitrate would probably occur over a larger area. This would decrease the intensity (per m²) of primary production. The long-term trend and the El Niño condition would result in a decrease in the intensity of primary production and therefore reduced fish production (Ryther 1969). Similarly during the winter months when upwelling is strongest the method of calculating the intensity of primary production appears biased toward larger values.

The species composition of the phytoplankton should also be affected by the long-term trends and El Niño. A deeper thermocline implies stronger poleward transport. Increased poleward currents appear to favor small offshore organisms as opposed to diatoms. Dinoflagellates are favored by weak winds (Chavez 1987b). The long-term trends suggest that conditions unfavorable to diatoms and dinoflagellates are developing. Colonial diatoms are considered the organisms which are most efficiently converted to fish production (Ryther 1969) so the long-term trend would be for less efficient conversion of primary production into fish production. The decrease in the abundance of dinoflagellates would lower larval anchoveta

Nótese que la eficiencia de transferencia fue de 2-3% durante el período de alta biomasa y producción de anchoveta (ej. los años de 1960).

survival, since dinoflagellates are the preferred food of the larvae (Lasker 1978), and eventually affect recruitment levels.

The results summarized in Table 1 suggest that the estimates of primary productivity calculated using the methods developed here are accurate. The results confirm that the primary production of the Peruvian upwelling system is substantially higher than that estimated by Ryther (1969) and Cushing (1971) (Chavez and Barber 1985). With the more accurate monthly estimates of primary production in Table 2 it is now possible to determine the proportion of primary production which was converted into anchoveta production for the entire time series. To estimate production of anchoveta (P), we have multiplied the monthly anchoveta biomass (B, wet weight) estimates of Pauly et al. (1987) by their estimates of total mortality ($Z =$ fishing mortality + natural mortality from all causes), and estimated production as $P = Z * B$ (Allen 1971). These estimates were then turned into carbon production estimates, using as conversion factor the average of Ryther's (10) and Cushing's (17.85) factor of carbon to wet weight ($0.072\text{gC} = 1\text{ g ww}$). The percentage that this represents of the total production is plotted in Fig. 13. This suggests that during the periods of maximum anchoveta biomasses, 2-3% of the total primary production was converted to anchoveta production.

Assuming that the gross food conversion efficiency of anchoveta is between 10 and 20% (Walsh 1981), the 2-3% converted to anchoveta flesh would correspond to between 10 and 30% of primary production. However, this range which would have applied during the period of maximum anchoveta abundance (in the 1960s) is realistic only if anchoveta fed exclusively on phytoplankton (which is not the case, see Rojas de Mendiola, this vol., Alamo, this vol. and Pauly et al., this vol.). Walsh (1981) suggested that the changes in anchoveta biomass which occurred in the early seventies would result in increased carbon accumulation in the sediments. However, the changes in the carbon flow from primary production to anchoveta production do not appear to be of sufficient magnitude to support this hypothesis which was also rejected by Henrichs and Farrington (1984), based on the lack of notable differences in the sediment organic carbon deposition rates before and after 1971.

Abstract

Different models of upwelling nitrate flux along the Peruvian coast are derived and compared. It emerged that realistic estimates of nitrate flux, and hence of new primary production, can be obtained only if the selected model incorporates a realistic gradient of nitrate concentrations, a variable upwelling depth and a variable width of the upwelling area along the Peruvian coast. Model outputs, i.e., monthly estimates of primary production for the period 1953 to 1982 are provided in tabular form for different parameterizations.

Resumen

Diferentes modelos para la surgencia de flujos de nitratos a lo largo de la costa peruana son derivados y comparados. Se encontró que estimaciones realistas de flujo de nitratos, y a partir de este de la de nueva producción primaria, pueden ser obtenidas solamente si el modelo seleccionado incorpora un gradiente realista de concentraciones de nitratos, una profundidad variable de surgencia y una anchura variable del área de surgencia a lo largo de la costa. Los resultados del modelo, es decir, estimaciones mensuales de producción primaria, para el período de 1953 a 1982 son proporcionados en forma tabular para las diferentes parametrizaciones.

Introduction

The primary production in the Peruvian upwelling system is known to fluctuate widely. Estimates vary more than one order of magnitude (see, e.g., Guillén and Calienes 1981; Feldman 1986) and are not available on routine basis. However, routine measurements of physical parameters, such as local wind speed, are available. Physical data recently made available by Pauly and Tsukayama (1987) may be used to parameterize newly upwelling nitrate. Thus, based on wind data and some ancillary data, Chavez et al. (this vol.) derived time series of the potential new production of the Peruvian upwelling ecosystem, with a mean of about $3.2 \text{ gC m}^{-2} \text{ day}^{-1}$.

Here we compare three models and two sets of physical parameters used to compute the upwelling nitrate in coastal and oceanic zones off Peru. The approach of Chavez et al. (this vol.) shall herein be referred to as Model I.

Data

The physical data used are time series of monthly mean of upwelling index, sea surface temperature, and depth of the 14°C isotherm. The upwelling indexes have been calculated from wind measurements at Trujillo (8°S) on the Peruvian shore (Mendo et al. 1987) and ship measurements in Peruvian coastal waters from 4°-14°S (Bakun and Mendelsohn, this vol.). Local and spatially averaged SST are given by Pauly and Tsukayama (1987) and Bakun (1987) respectively and isotherm depths by Brainard and McLain (1987) for coastal Peruvian waters. The chemical data are measurements of nitrate concentration (and SST) taken on cruises carried out by IMARPE during 1981-1987.

Theory

The parameterization of primary production relies on the assumption that the upwelled waters contain a limiting nutrient (nitrate) required by phytoplankton. New primary production will therefore be proportional to the upwelled water mass and the concentration of nitrate. The first step in modelling new primary production is thus to parameterize the upward flux of nitrate.

The divergence-induced upwelling in depths of the Peruvian coastal current system is the source of the upwelled water masses. Their actual upwelling to the surface is due to the wind-induced Ekman pumping. Consequently, upwelling depths change as a function of the wind (Guillén and Calienes 1981).

Model I relies on the correlation of the depth of the 14°C isotherm and nitrate concentration in 60-m depth. Also, the time series of isotherm depths was interpreted as a measure of the mean nitrate concentration of the upwelled water masses. The product of the upwelling index, basically the square of the wind speed, and isotherm depth would thus be a measure of the upwelled nitrate which may then be converted into an estimate of new primary production.

Our model of the vertical nitrate flux differs in three elements from Model I. First, the nitrate concentration above the thermocline changes with depth; it is lowest near the surface. Second, the water masses upwelled to the surface originate from different depths depending on the actual wind speed. Third, the width of the upwelling region, measured by the internal Rossby radius of deformation, changes with the thermal stratification. This model, described below, leads in contrast to Model I, to a measure of the vertical nitrate flux which is proportional to the third power of the ratio of wind speed and depths of the 14°C isotherm divided by the surface temperature.

The concentration of nitrate (μM) at 60 m depth is, in Model I, linearly correlated with the depth of the 14°C isotherm ("D₁₄").

$$\text{CNO}_3 = a - b * D_{14} \quad \dots 1)$$

where $a = 44.15 \mu\text{M}$ and $b = 0.20 \mu\text{M}\text{m}^{-1}$ and $r = -0.82$.^a

The vertical nitrate flux per unit length of coast line as a function of the upwelling "Up" ($\text{m}^3\text{sec}^{-1}\text{m}^{-1}$) is:

$$F_{\text{NO}_3} = \text{CNO}_3 * \text{Up} \quad \dots 2)$$

The strength of the upwelling is proportional to the longshore wind speed squared. The nitrate concentration at the surface is generally considerably less than in deeper waters (Caliernes and Guillén 1981). The difference is most pronounced during periods of warm anomalies, i.e., El Niño events. Thus it might be assumed, as a first approximation that the surface concentration is negligible when compared to the concentration in deeper waters. However, it would be better to parameterize the surface nitrate concentrations by the surface temperature. Using data collected

^aChavez et al. (this vol.) use micromolar (μM) to express concentrations (i.e., $\mu\text{g-at./l}$); further below we use the equivalent mmol.m^{-3} .

in the region 7°-10°S by IMARPE (during February and August 1981, December 1982, January 1983, February, July and August-September 1985, April-May 1986 and February 1987) suggests the parameterization (Fig. 1):

$$\log(C(O)) = \log(A) - B * \log(SST) \quad \dots 3)$$

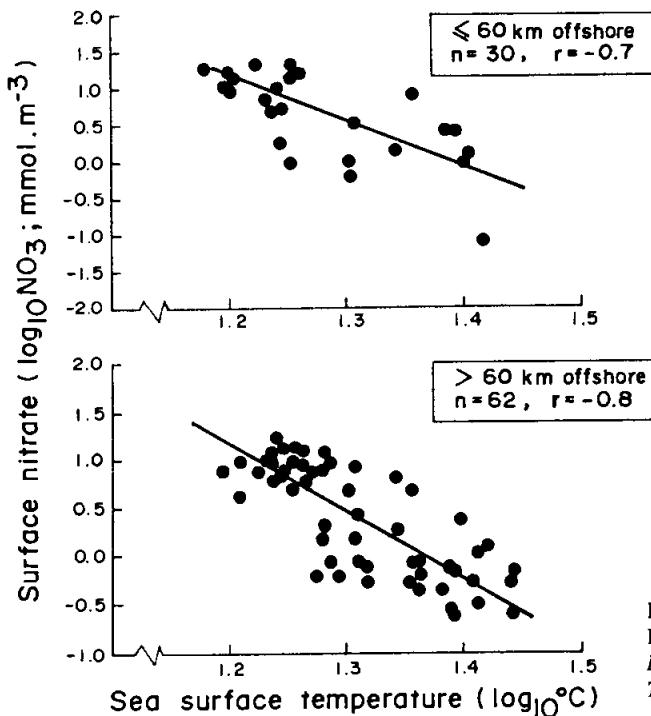

Fig. 1. Regression of nitrate concentration in surface waters vs. SST off Peru. Above: coastal zone. Below: oceanic zone.
Fig. 1. Regresión de concentración de nitratos en agua superficial vs. TSM frente a Perú. Arriba: zona costera. Abajo: zona oceánica.

where the units are mmol.m^{-3} and $^{\circ}\text{C}$, and where the parameters "a" and "b" vary with offshore distance, i.e.,
 $\leq 60 \text{ km offshore: } \log(a) = 8.57 \text{ } b = -6.18$
 $> 60 \text{ km offshore: } \log(a) = 9.48 \text{ } b = -6.93$

The 14°C isotherm generally occurs at depths around 120 m. Thus, taking the estimates of nitrate concentration at the surface and at 60 m depth, the vertical profile of newly upwelled nitrate above the thermocline may be approximated as

$$C(z) = C(O) + 2 * (C_{NO_3} - C(O)) / D_{14} * z \quad \dots 4)$$

where z is the depth and which reduces, for vanishing surface concentration, to

$$C(z) = 2 * C_{NO_3} / D_{14} * z \quad \dots 5)$$

The upwelling of subsurface water takes place at the bottom of the wind driven Ekman layer. Its thickness " D_E " can be estimated as a function of the wind speed (U) using scaling laws given by Csanady (1982):

$$D_E = c * U \quad \dots 6)$$

Thus, the nitrate concentration in the upwelled water is

$$C(D_E) = (C(O) + 2 * (a - b * D_{14} - C(O) / D_{14}) * c * U) \quad \dots 7)$$

with

$$\begin{aligned}a &= 44.15 \text{ mmol.m}^{-3} \\b &= 0.20 \text{ mmol.m}^{-3} \\c &= 6.222 \text{ s}\end{aligned}$$

The vertical flux of nitrate per unit length of the coast line can be compared to equation (2):

$$F_{NO_3} = C(DE) * U_p \quad \dots 8)$$

The internal Rossby radius "R_i", the measure of the width of the upwelling zone, can be estimated using different approaches, depending on the physics to be described. Here we use a formula which assumes two-layered stratification: a warmer upper layer of thickness "h₁" extending from the surface down to the depth of the 14°C isotherm, and a colder lower layer of thickness "h₂" extending from the 14°C isotherm, down to the bottom. The interface is described by its depth (D₁₄) and a normalized mean density difference "e" which is a function of the temperatures of the top and the bottom layers. The first is understood as a function of SST and the latter is set to 12°C.

Density differences depending on salinity changes are not incorporated because of lack of data. The temperature and salinity ranges found offshore of Peru (Guillén et al. 1977; Zuta et al. 1978) indicate that density differences are mainly a function of temperature. However, the estimate of the internal Rossby radius given below is nothing more than a first order approximation formulated such as to vary with season and the occurrence of El Niño events:

$$R_i = (g * e * (h_1 * h_2 / h_1 + h_2))^{1/2} / f \quad \dots 9)$$

$$\begin{aligned}e &= E * (T_a^2 - 8^\circ * T_a - 4^\circ * 12^\circ) \\T_a &= (14^\circ + SST) / 2 \\h_1 &= D_{14} \\h_2 &= 250 \text{ m} - D_{14} \\E &= 7.3 \cdot 10^{-6} (\text{°C}^{-2}) \\g &= 9.81 \text{ (ms}^{-2}\text{)} \\ \text{and } f &= 2.283 * 10^{-5} (\text{rad s}^{-1}; \text{at } 10^\circ\text{S})\end{aligned}$$

The mean reference bottom depth of 250 m has been chosen as reference value for the entire region to which the model is applied. This value fits the nearshore (shelf) conditions but is too low for offshore conditions over the continental slope.

Some comments on the Rossby radius should be made. It is a measure of the width of the coastal upwelling zone, i.e., there is an exponential decrease of the upwelling to 25% over distances of the order of one Rossby radius.

Estimates of the Rossby radius based on equation (9) are most sensitive to changes of the interface depth if the reference bottom depth is about twice the interface depth. If the reference bottom depth is several times larger than the interface depth, then estimates of the Rossby radius of deformation are not too sensitive to different values for the reference bottom depth. Here, the seasonal fluctuations of the Rossby radius as a function of the changing stratification is the feature to be parameterized. Thus, the parameterization of the Rossby radius is set to mirror temperature-dependant changes of stratification.

A constant estimate of Rossby radius derived from the phase speed (about 2.5 ms⁻¹) of internal Kelvin waves (Romea and Smith 1983) has been used in Model I. Estimates of average Rossby radius for regions of large latitudinal extent in low latitudes, as in this case, must be very approximate. The Rossby radius in 5° and 15°S is about 220 km and 73 km, respectively, if derived from the internal phase speed of Kelvin waves. These estimates are several times higher than those which will be used here (Fig. 2), because they rely on a dynamic (Kelvin wave) which is sensitive to the abyssal depths off the continental margin. This would be meaningful if the coastal upwelling is due to Kelvin waves and not due to deep divergence of the Peruvian coastal current system and to Ekman pumping. However, in view of the latitudinal dependence of the Rossby radius, any useful parameterization should be such that it is not too sensitive to the mean value of the Rossby radius, but rather responds to its temporal, especially seasonal, changes (Fig. 2).

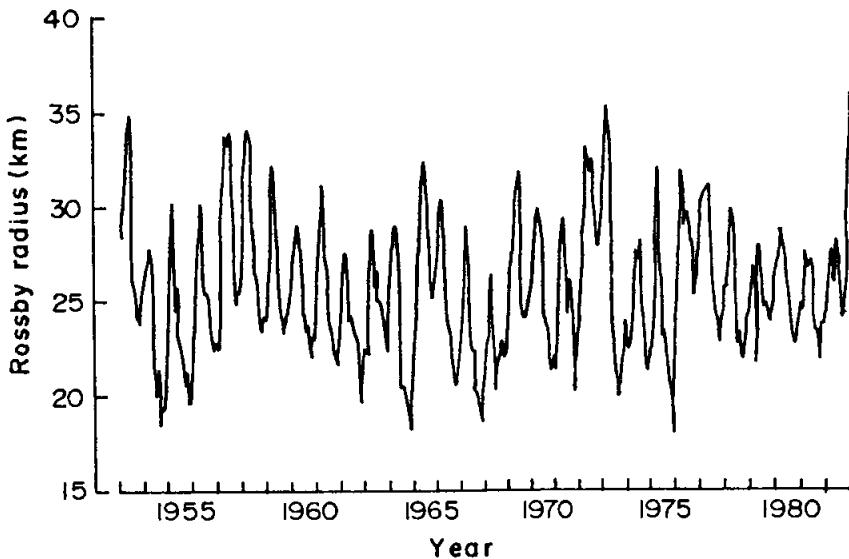

Fig. 2. Time series of the mean Rossby radius of deformation for the area 4-14°S off Peru, as estimated with local SST and depth of the 14°C isotherm.

Fig. 2. Series de tiempo del radio de deformación de Rossby medio para el área 4°-14°S frente a Perú, calculadas con TSM local y profundidad de la isoterma de 14°C.

Upwelling decreases from the coastline. The latter is, in this context, the isobath for which the surface wave field is not yet influenced by the bottom topography (this starts at about 50 m), or the isobath which separates roughly the nonhydrostatic inshore from the hydrostatic offshore dynamics. The strength of the upwelling will be about 5% of its maximum value, which occurs at the coast line, at positions three times the Rossby radius seaward of the coast line. The strength of the upwelling is measured by the upwelling index which gives the mass flux by unit length of coast line. Thus, the nitrate flux per unit surface will be obtained for both models of the nitrate flux per unit coast line (equations 2 and 8) via:

$$f_{\text{NO}_3} = F_{\text{NO}_3}/(R_i * 3) \quad \dots 10)$$

The estimates of nitrate flux per unit surface depends on (1) the model of the nitrate concentration at depth and (2) the parameterization of the upwelling. The version of our model following most closely that in Model I is characterized by homogeneous nitrate concentration and a fixed upwelling depth. This model will be called here the "constant depth model" or "CDM". Our complete model includes nitrate concentration which increases with depth and a variable depth from which the water is upwelled by Ekman pumping. This model will be labeled "variable depth model" or "VDM". Both models are used together with an upwelling zone of variable width (three Rossby radii), thus incorporating lateral variability. In this context, Model I is characterized as: homogeneous nitrate concentration, fixed upwelling depth and fixed width of the upwelling region. The three models thus form a hierarchy of models of increasing complexity (Model I < CDM < VDM).

Results and Discussion

In the following, the models of the vertical nitrate fluxes are compared, and differences due to the use of two distinct descriptions of the wind field will be presented. In a second step, we convert the nitrate fluxes to the new primary production of organic carbon by the Redfield ratio and a global efficiency factor of 0.75. These estimates are then compared to independently obtained measurements of primary production.

In order to compare correctly, one has to consider (1) that the regressions between nitrate concentration and temperature or isotherm depths are only crude estimates (the square of the correlation coefficients is about 0.5, thus only 50% of the variance is explained), and (2) that the model contains several more or less unknown parameters whose values may be selected such as to "tune" the model to any preselected conditions. Therefore, even if we trust the model itself, we cannot expect to find close agreement to observations. However, the key features of the model outputs should be consistent with observations.

The time series of surface nitrate concentrations were estimated by regression (equation 3) from the time series of the spatial mean SST and local SST (mean of values off Talara, Chimbote and Callao). Fig. 3, which shows their long periodic variability (twelve-monthly running mean), implies that the upwelling at the coast (≤ 60 km offshore) is stronger than in the oceanic zone (> 60 km offshore). Minima of the nitrate concentrations occur during periods of maximal SST (El Niño events). The difference in surface nitrate concentrations in the coastal and in the oceanic zone appear to have increased since the late 1960s. This feature is due to the different behavior of the time series of local and mean SST since the late 1960s (see Brainard and McLain 1987).

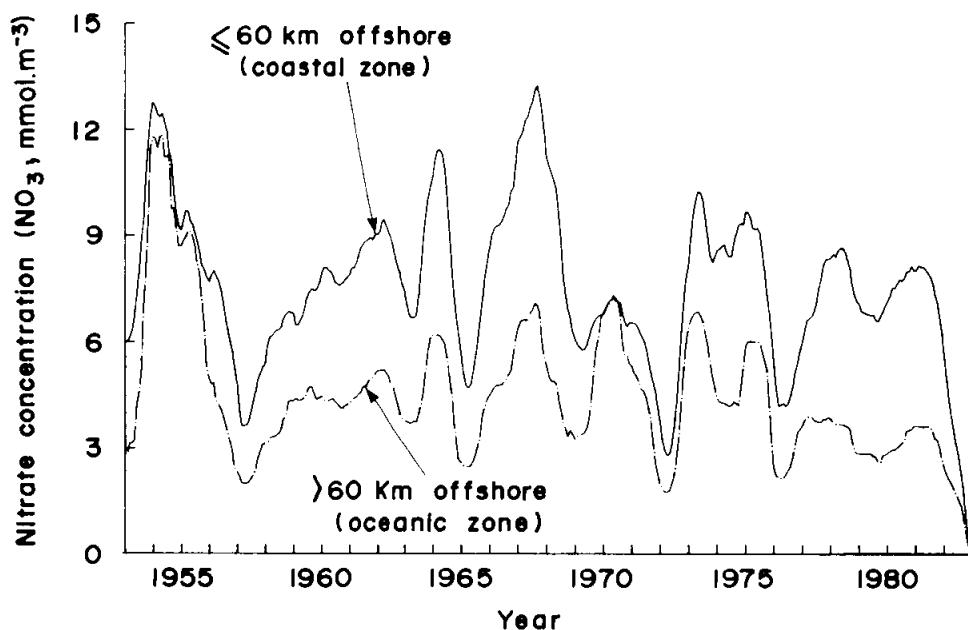

Fig. 3. Smoothed time series of nitrate concentration in Peruvian surface waters (coastal and oceanic zones, 4° - 14°S). Note impact of El Niño events (arrow).

Fig. 3. Series de tiempo suavizadas de concentración de nitrato en aguas superficiales peruanas (zonas costera y oceánica, 4° - 14°S). Notar el impacto del evento El Niño (flecha).

Thus, the time series of nitrate concentration behave reasonably and match concepts and observations (Caliñes et al. 1985). This result justifies the use of two different sets of upwelling indexes, one for the coast (Trujillo upwelling) and one for the oceanic zone (Bakun's upwelling), to describe the vertical fluxes. Therefore, both models will be applied to two different regimes, one determined by the coastal parameter setting (SST to NO_3 , Trujillo winds) and the other determined by the oceanic parameter setting (SST to NO_3 , Bakun's winds). In both cases, the same estimates of the Rossby radius (Fig. 2) have been used.

It should be noted that most of the variability of the Rossby radius is due to seasonal fluctuations; the seasonal estimates differ roughly by a factor of 1.5; and minimum and maximum values are about 20 km and 30 km, respectively. This means that the width of the upwelling zone (equation 9) varies between 60 and 90 km. This seems to be a reasonable estimate if compared to observations of the width of the coastal zone of high productivity (Caliñes et al. 1985) or low SST (Zuta et al. 1978). Also, the seasonal variability of the Rossby radius and of the wind-induced upwelling is well reproduced in the monthly fluctuations of nitrate flux (Fig. 4).

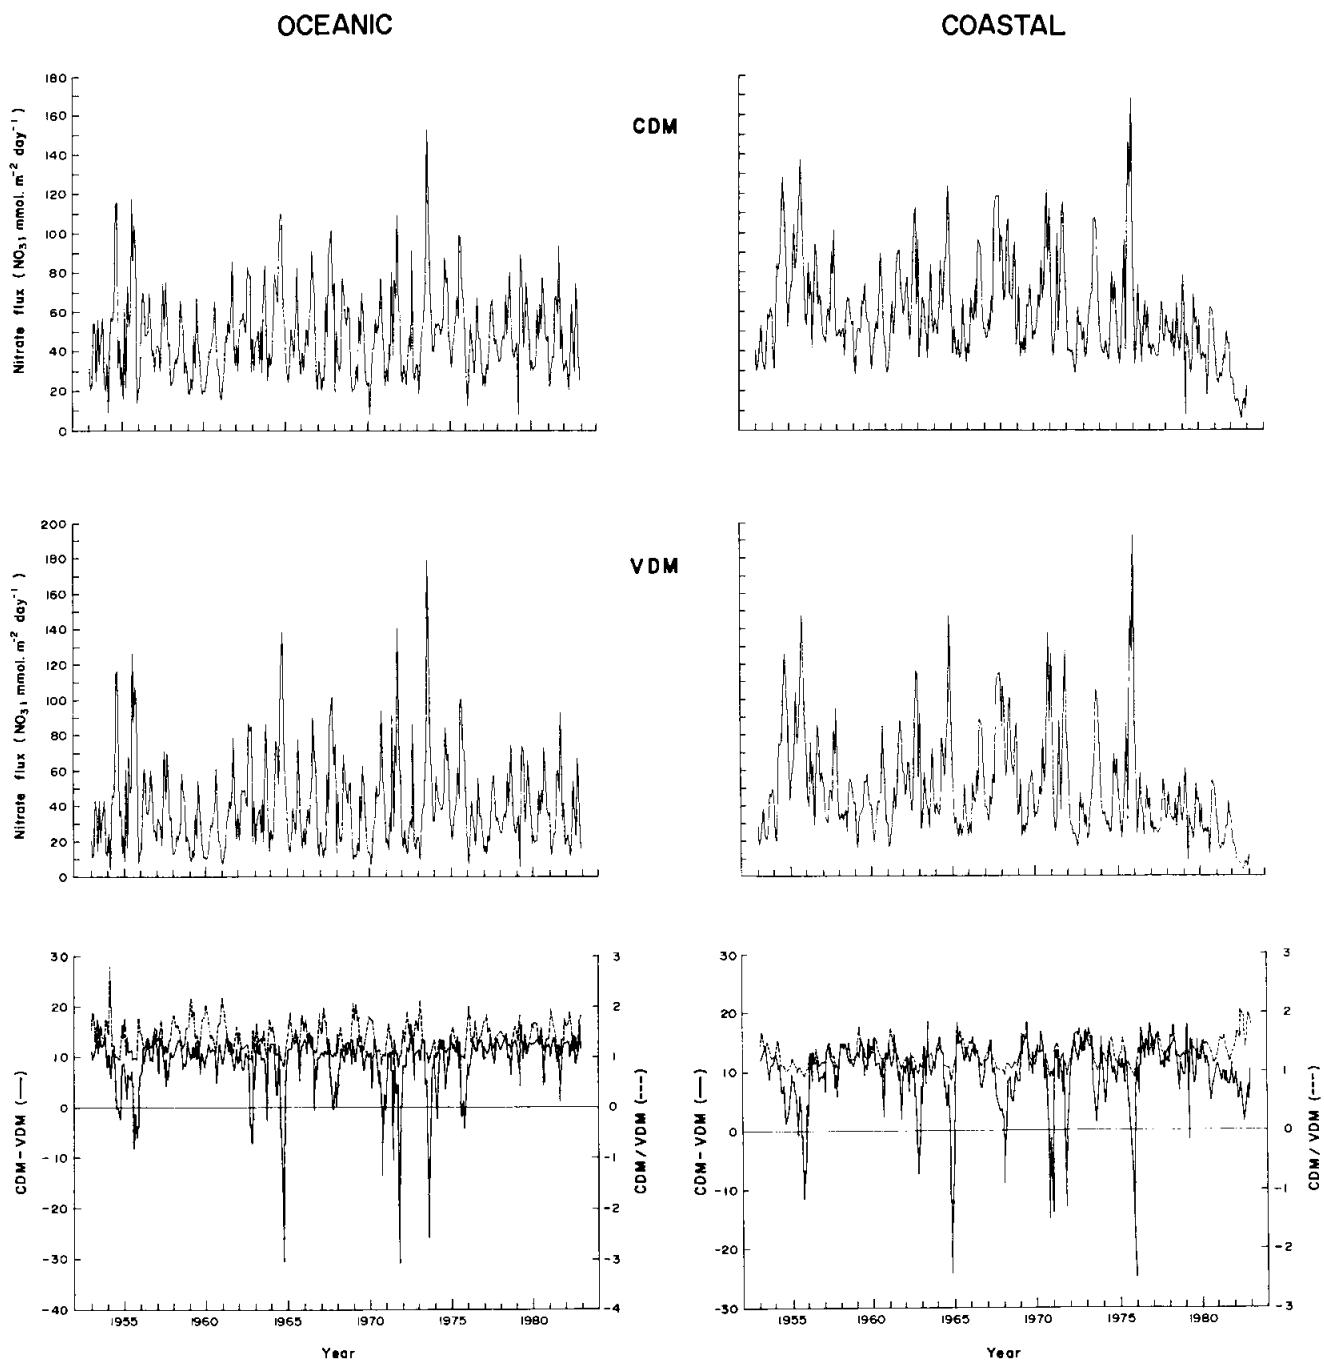

Fig. 4. Upper and central graphs: monthly estimates of upwelled nitrate off Peru, as obtained from "constant depth model" (CDM) and "variable depth model" (VDM), for oceanic and coastal settings. Lower graphs: relationship between CDM and VDM estimates.

Fig. 4. Gráficos arriba y centro: estimaciones mensuales de nitratos frente al Perú, obtenido del "modelo a profundidad constante" (CDM) y el "modelo a profundidad variable" (VDM), usando parámetros oceanicos y costeros. Gráficos abajo: relación entre las estimaciones con CDM y VDM.

The complete, variable upwelling depth model (VDM) yields nitrate fluxes which are generally lower than those using the constant upwelling depth model (CDM) (Figs. 4 and 5). Similar estimates obtained by the CDM are obtained for situations of high nitrate fluxes and this feature is independent of the use of coastal or oceanic parameter setting.

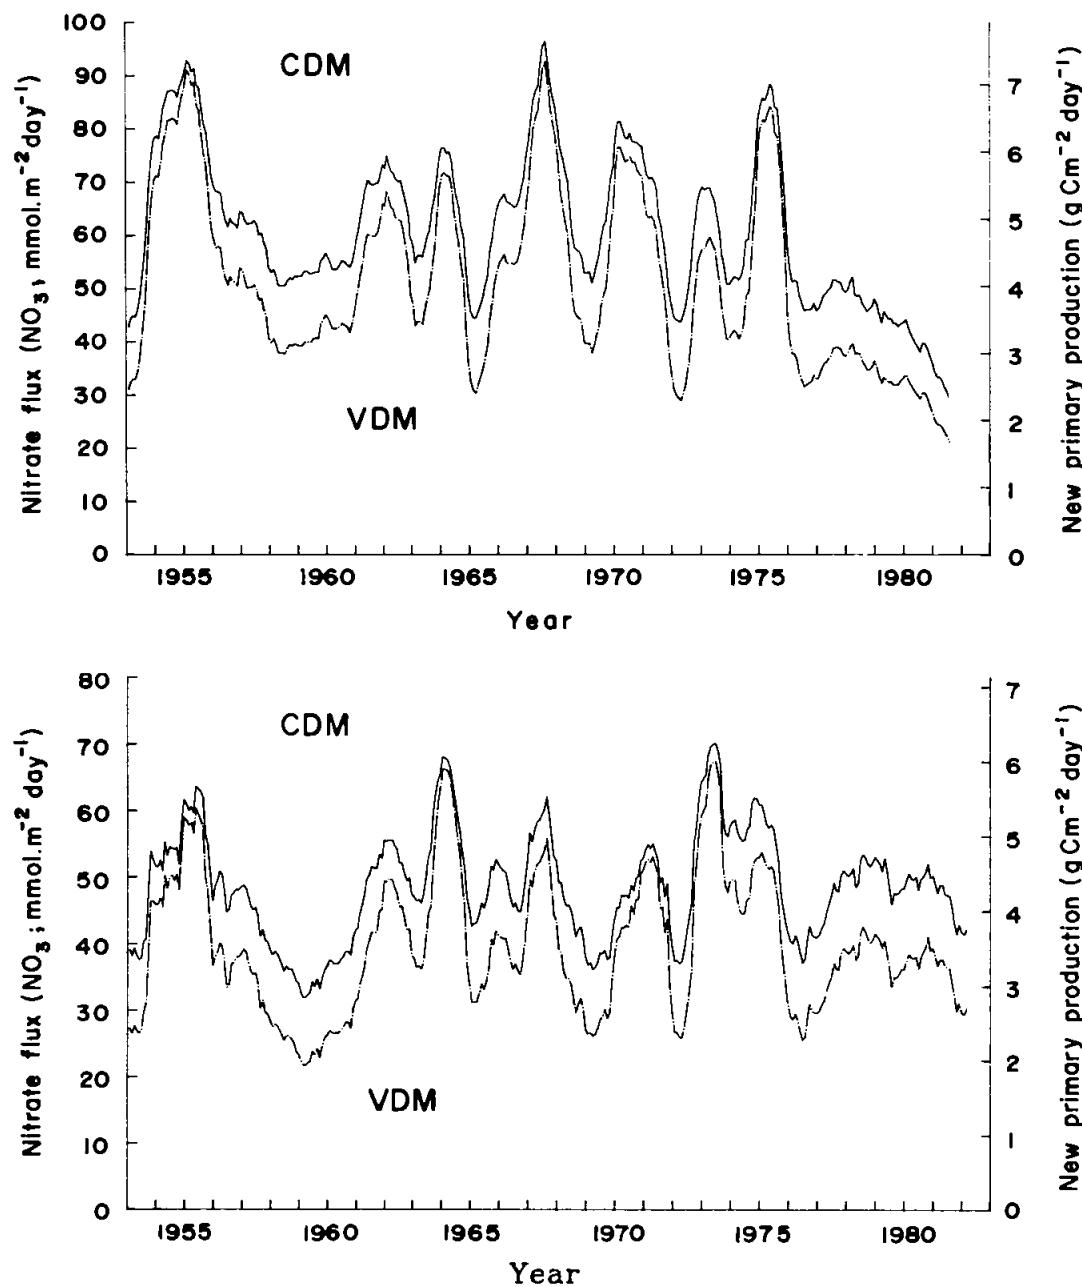

Fig. 5. Smoothed nitrate fluxes per unit sea area off Peru. Above: coastal zone (based on Trujillo upwelling index). Below: oceanic zone (based on Table 1 in Bakun and Mendelsohn, this vol.). The right scale (see text) expresses the same data as time series of new primary production.

Fig. 5. Flujos de nitrato suavizados por unidad de área frente a Perú. Arriba: zona costera (basado en el índice de surgesencia de Trujillo). Abajo: zona oceánica (basado en Tabla 1 en Bakun y Mendelsohn, este vol.). La escala a la derecha (ver texto) expresa los mismos datos de las series de tiempo de nueva producción primaria.

Thus, seasonal variability is increased if nitrate concentrations as a function of depth and variable upwelling depths are included in the model. The differences concern mainly lower estimates of upwelled nitrate per unit surface for southern hemisphere summer. Calienes et al. (1985) report ratios of mean seasonal surface concentration of nitrate summer to winter of about 1 to 3. This seems to be closer to the range given by the VDM, but the CDM does not fall off significantly. Seasonal variability is slightly higher for the coastal than for the ocean parameter setting.

The smoothed time series (twelve-month running mean) of the nitrate fluxes per unit surface (Fig. 5) show that both models give the same mean estimate for well established "cool events" but differ considerably for "warm events", (i.e., El Niño events) and this obviously also applies

to our estimates of new primary production which are mathematically nothing more than rescaled estimates of nitrate flux (see Fig. 5). The mean values of both models could have been tuned to match each other by, e.g., plugging a higher constant "c" in the parameterization of the depth from which the water is taken by Ekman pumping. However, this would only mask the systematic differences between both models.

Fig. 5 also shows the net effects of the coastal and oceanic parameter setting. Mean levels of nitrate flux or new primary production are higher for the coastal setting. However, the differences are about 1 gCm⁻²d⁻¹, which is within the range of differences between the two models. The sequence of peak and troughs in the time series differ, especially for the 1960s. This indicates, if it is assumed that both parameter settings really depict coastal and oceanic conditions, that nitrate upwelling and primary production have different temporal changes near- and offshore. This, too, appears consistent with the spatial variability of the physics of the Peruvian upwelling system (Brink et al. 1983).

Guillén et al. (1977) report a ratio of primary production between "normal" and the 1972 El Niño event of about 4 to 1. This ratio is higher than any modeled peak to trough ratio found for the smoothed time series but could be met by the peak to trough ratios of the unsmoothed monthly values. However, the mean values estimated by the model, about 4 gCm⁻² d⁻¹ or 2 gCm⁻² d⁻¹, are much higher than the observations (a problem which could be circumvented by selecting a different factor for converting nitrate flux to primary production - see above).

Comparing both models in terms of monthly mean values of the daily new production per m² illustrates (see Fig. 4C, D) the features discussed above. The new primary production is

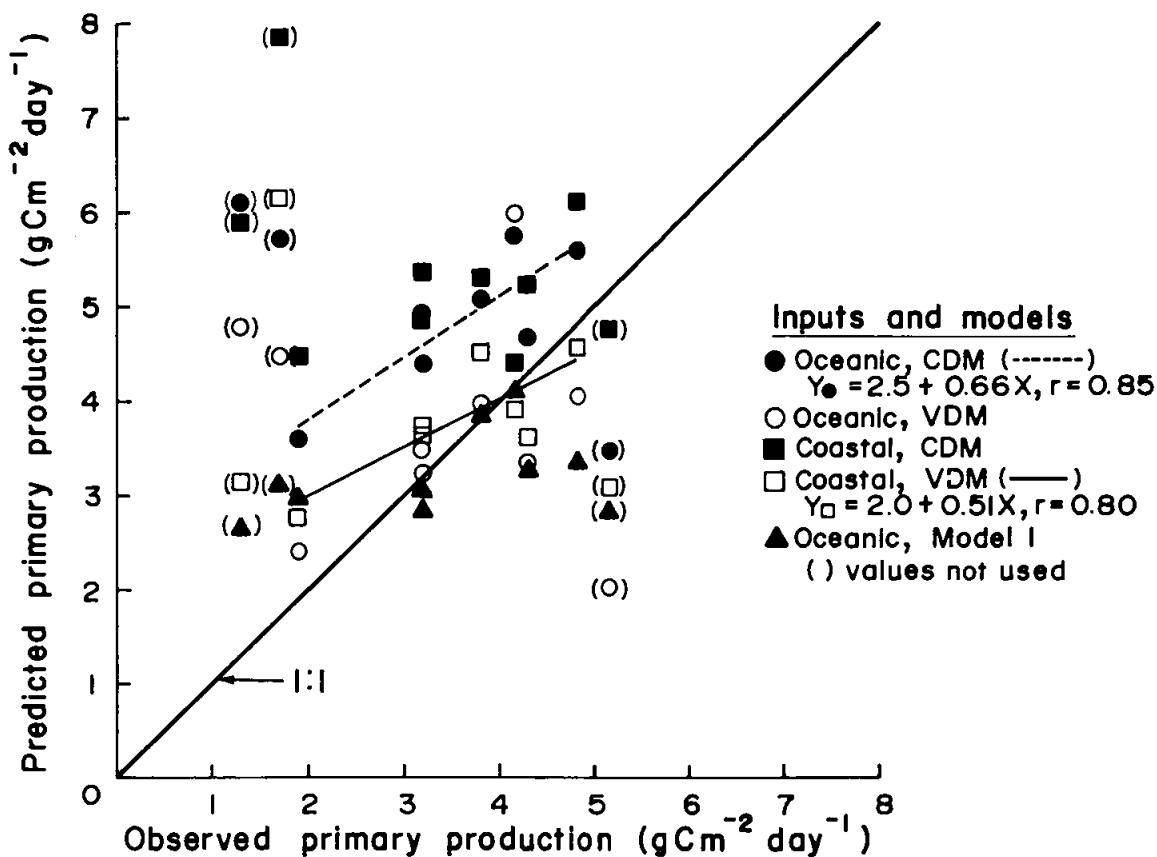

Fig. 6. Estimates of primary production relationships between observed (C_{14} method) and predicted primary production. The two regressions and their correlation coefficients refer to the two significant correlations of models and observations. Some observations (in brackets) were not used in the regression (see text for details).

Fig. 6. Estimaciones de producción primaria: Relaciones entre valores observados (método del C_{14}) y producción primaria pronosticada. Las regresiones y sus coeficientes de correlación se refieren a las dos correlaciones significantes de los modelos y observaciones. Algunas observaciones (en paréntesis) no fueron usadas en la regresión (ver texto para detalles).

Table 1. Comparison of observed and modelled estimates of primary production in $\text{gCm}^{-2}\text{day}^{-1}$ (unsmoothed) in the Peruvian upwelling system. Models have been used for two parameter settings (coastal, oceanic) and rely on two hypotheses: (a) upwelling from fixed depth (CDM), and (b) upwelling from variable depth and vertical profile of nitrate concentration (VDM). The potential new production was converted to total production using a ratio of new to total production of 0.75 (Dugdale 1985). Dates marked "*" refer to measurements performed under conditions not compatible with the models (see text for details).

Tabla 1. Comparación de estimaciones de producción primaria en $\text{gCm}^{-2}\text{día}^{-1}$ (no suavizadas) observadas y modeladas en el sistema de afloramiento peruano. Se usaron modelos para dos parámetros (costero, oceánico) y se basan en dos hipótesis: (a) Surgencia desde una profundidad fija (CDM), y (b) surgencia de profundidades variables y perfiles verticales de concentración de nitratos (VDM). La producción nueva potential fue convertida a producción total usando un factor de conversión de producción nueva a total de 0.75 (Dugdale, 1985). Fechas marcadas con "" se refieren a medidas hechas bajo condiciones no compatibles con los modelos (ver texto para detalles).*

^aFrom Table 1 in Chávez et al. (this vol.)

generally about 1 $\text{gCm}^{-2}\text{d}^{-1}$ higher if parameterized via the CDM. The ratios of model estimates scatter less for the coastal setting. This feature is reasonable because upwelling is strongest near the coast and vertical gradients are therefore less pronounced. The VDM estimates the highest production, about 1 to 2 $\text{gCm}^{-2}\text{d}^{-1}$ higher than the CDM does during pronounced cool events. A spectacular difference of both model is found for the coastal setting in southern hemisphere winter 1982. Both estimates differ by a factor of more than 2 for several months compared to an overall ratio of about 1.5. This feature indicates important changes of the nitrate concentration with depth and weak upwelling. Upwelling indexes at Trujillo are small, about 25% of their normal values (Mendo et al. 1987), the 14°-isotherm is relatively deep (150 m), about 20 m below normal, and SST is relatively high (16°C), about 1°C above normal (Brainard and McLain 1987). The nitrate profile corresponding to these values is steeper than normal and upwelling is from depths above 60 m. Thus, the CDM should overestimate the vertical nitrate fluxes during the onset of the 1982-1983 El Niño event. CDM and VDM show no different estimates for the oceanic setting, because winds are about normal (Bakun 1987).

Using Dugdale's (1985) estimate of the "f" factor for the Peruvian upwelling system, the new production was converted to total production in order to compare our estimates to estimates made using C_{14} uptake reported in Chávez and Barber (1987). Numbers are given in Table 1 and refer to unsmoothed monthly estimates. Their relationships, compared to the expected slope of one, are shown in Fig. 6. This figure shows estimated production vs. measured production. Any good approximation of the measurements by the model should yield a scatter of points about a line with slope one.

First, Model I (constant upwelling depth and fixed width of the upwelling zone) and our models CDM and VDM used with coastal and oceanic parameter setting respectively, do not describe the tendency found in the C_{14} uptake measurements (i.e., the linear regressions lead to

slopes of about 0.1, while the correlation coefficients are about 0.6). Those are the best estimates (minimum confidence interval for r) which may be achieved after dropping of extreme values. Thus, no reasonable relation exists between measurements and model estimates.

Our models CDM and VDM used for the oceanic and coastal parameter setting respectively match the observations relatively well (see Fig. 6). The correlation coefficients, while not high, are in the order of those coefficients which relate the nitrate-temperature relationships. Also, the computed slopes are less than, but not statistically different from one. The slopes are different from slope zero at the 80% confidence level. However, care should be taken for any statistical interpretation because the number of points is low. It seems that both models underestimate high productivities and overestimate low productivities. This effect is stronger for the CDM, which as in Model I, incorporates the idea of a constant upwelling depth along with a variable width of the upwelling region. It is concluded that both variable upwelling depths and variable width of the upwelling zone are important features which are needed for correct representation of the processes described here.

Second, phenomena occurring in April and June 1969 as well as in April 1977 are outside the range of phenomena described reasonably well by the models. Two events resulting in low production were overestimated and one event in high production was underestimated.

Third, the model incorporating a variable width of the upwelling zone and a fixed upwelling depth overestimates primary production by about 1 gCm⁻² d⁻¹, whether production is high or low. The median values (Table 1) of both models differ by about 1.6 gCm⁻² d⁻¹. This difference is too low to be statistically significant, but the regression suggests systematic overestimation by the model using a constant upwelling depth.

The estimate of monthly new primary production provided here as Tables 2 to 5 should be used with the foregoing in mind.

Abstract

Corrected values are presented for the monthly series of Peruvian alongshore stress presented in the previous volume of this series. The series is updated through 1986. The faulty "old" and corrected "new" series are compared and found to have very similar properties. It is concluded that studies based on the "old" series will not be significantly in error.

Resumen

Se presentan los valores corregidos del esfuerzo del viento a lo largo de la costa peruana, para las series mensuales dadas en el Volumen previo a este. La serie ha sido actualizada hasta 1986. Se compara la serie "antigua" defectuosa con la serie "nueva" corregida, encontrándose que ambas tienen propiedades muy similares. Se concluye que los estudios basados en la serie "antigua" no contienen error significativo.

Introduction

Bakun (1987) presented monthly indicator series for a number of environmental processes affecting the habitat off Peru. An error has been discovered in the computer program used to generate one of the reported series, that of the alongshore component of wind stress on the sea surface. Here we present corrected values for that particular series and also update the series through 1986 (Table 1).

Alongshore wind stress is one of the most important forcing functions for dynamic processes in the coastal environment. For periods of variation longer than a half-pendulum day (2.9 actual days at 10° latitude), the offshore transport which is directly driven by the wind (the offshore Ekman transport) is directly proportional to the equatorward alongshore wind stress, the constant of proportionality ($\sim 3.95 \times 10^4$ sec. for the latitude range of this particular series) being the reciprocal of the Coriolis parameter. To the extent that the flow divergence at the coast due to offshore surface transport is not balanced by convergence of alongshore flow, the water transported offshore is replaced by upwelling of deeper waters to the surface. Thus, variability in alongshore stress is reflected in variability in intensity of locally wind-driven coastal upwelling. Interyear variability in alongshore stress, often expressed either in terms of offshore Ekman transport or in terms of an "upwelling index", has been found to correlate with recruitment variability in a number of neritic fish populations (Bakun and Parrish 1980; Shepherd et al. 1984; Bakun 1985).

The computations and procedures employed in generating the updated corrected series (Table 1) are those outlined by Bakun (1987), except that the data for 1985-86 is from the COADS dataset rather than from the TDF-11 dataset.

Table 1. Alongshore component (positive equatorward) of wind stress on the sea surface. Units are dynes per square centimeter. Values in this table multiplied by the factor 3.95 yield offshore Ekman transport in cubic meter per second across each meter width.

Tabla 1. Componente a lo largo de la costa (positivo con dirección ecuatorial) del esfuerzo del viento sobre la superficie del mar. Las unidades se dan en dinas por centímetro cuadrado. Los valores de esta Tabla al multiplicarse por 3.95 dan como resultado el transporte Ekman en metro cúbico por segundo por cada metro de línea costera.

Comparison and Reconciliation of the Two Series

Resolution of the alongshore component of the wind stress, τ_a , is according to

$$\tau_a = \alpha \tau_y - \beta \tau_x \quad \dots 1)$$

where τ_y and τ_x are the respective northward and eastward stress components; $\alpha = \cos\phi$ and $\beta = \sin\phi$, where ϕ is the angle, counterclockwise from true north, of the large-scale coastline trend. For the Peruvian coast a compass direction of 332° ($\phi = 28^\circ$) is chosen as the characteristic large scale coastline trend (i.e., $\alpha = 0.8829$, $\beta = 0.4695$).

In producing the series reported by Bakun (1987), the value 0.8829, appropriate to α , was also erroneously assigned to β . Since the wind stress off Peru is generally from the southwest (Bakun and Parrish 1982), τ_x would generally have a negative value. Thus the magnitude of the monthly estimate of τ_a would tend to have been amplified by the error. The computation of the onshore component of the wind stress and of the "wind cubed" index (Bakun 1987) are unaffected by this error.

Thus the power spectra of the "old" series from Bakun (1987) generally has higher values than the "new" corrected series (Fig. 1a). However, note that the shape of the spectra are quite similar, with high peaks at the annual frequency and the familiar "red noise" spectral shape at the low frequency end. Note also that the coherence (Fig. 1b) between the series is very high, being nearly 1.0 over the spectral peaks and falling somewhat lower only in spectral "gaps" where very little of the variance of the series is found. Also there is essentially no phase difference between the two series over the entire spectral range (Fig. 1c). Fig. 1 shows that the two series should be nearly equivalent for most applications, except in terms of magnitude.

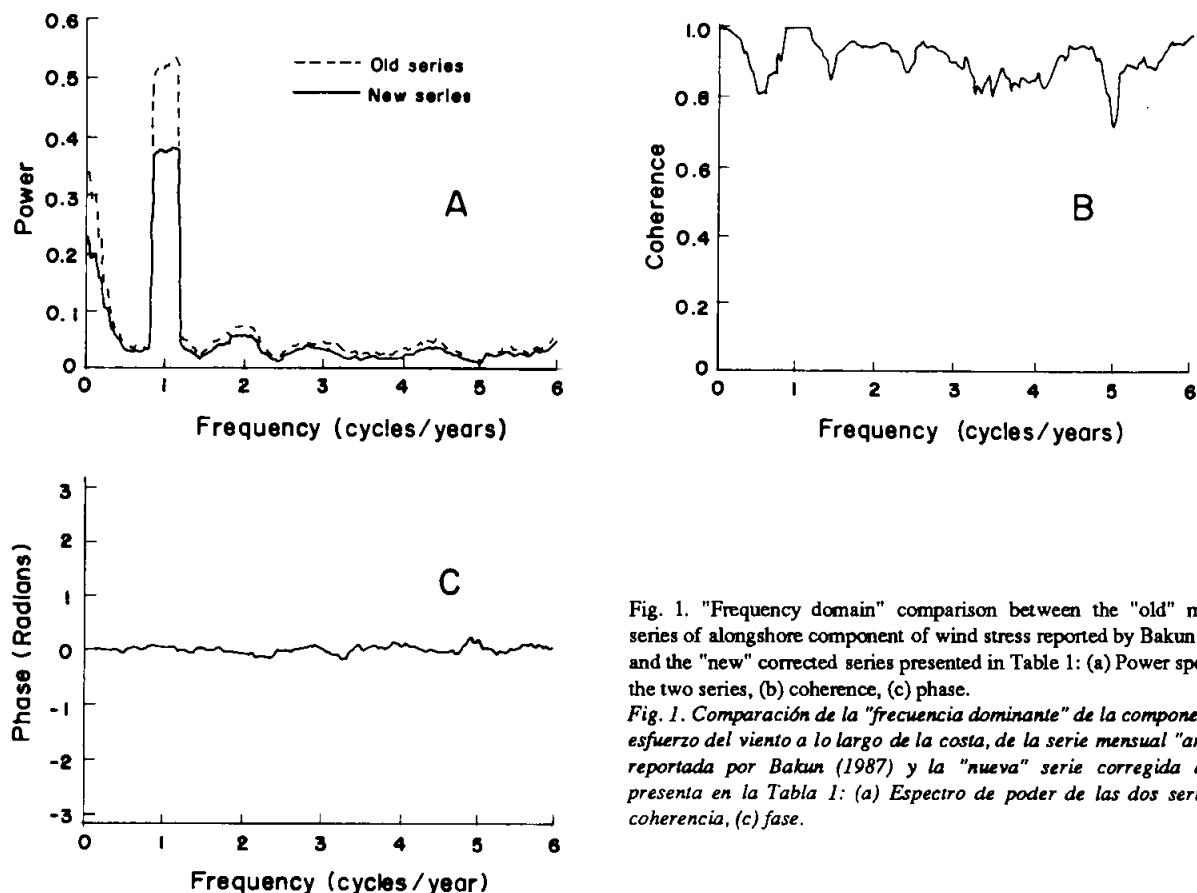

Fig. 1. "Frequency domain" comparison between the "old" monthly series of alongshore component of wind stress reported by Bakun (1987) and the "new" corrected series presented in Table 1: (a) Power spectra of the two series, (b) coherence, (c) phase.

Fig. 1. Comparación de la "frecuencia dominante" de la componente del esfuerzo del viento a lo largo de la costa, de la serie mensual "antigua" reportada por Bakun (1987) y la "nueva" serie corregida que se presenta en la Tabla 1: (a) Espectro de poder de las dos series, (b) coherencia, (c) fase.

For example, the seasonal pattern is very similar (Fig. 2), as are the major interannual features in the two series (Fig. 3). Both series indicate seasonal maxima in alongshore stress during austral winter (peak in September) and minima in summer (lowest in January). Both series show increases in alongshore stress associated with El Niño episodes and some indication of a general linear upward trend from the mid-1950s to 1982-83.

For readers who may be more comfortable with correlation coefficients than with coherence spectra, regressing the "old" series on the "new" series yields a correlation of $r = .975$ and a regression line slope of $b = 1.14$. Transforming the two series to "anomalies", by subtracting the

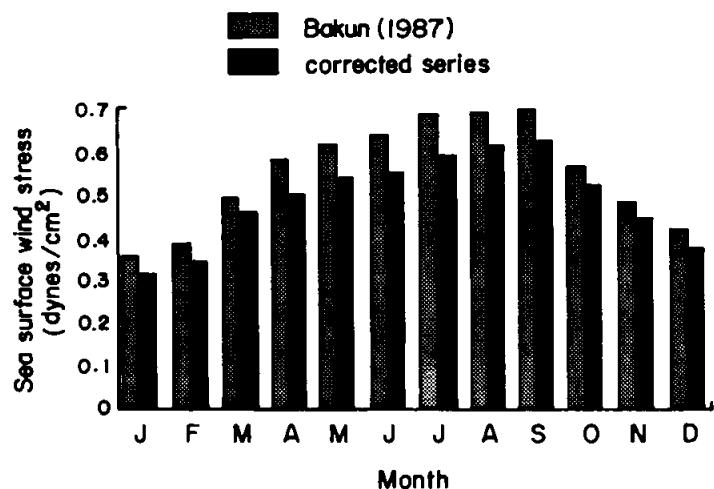

Fig. 2. Seasonal pattern (long term 1953-84 mean monthly values) of the "old" monthly series of alongshore component of wind stress reported by Bakun (1987) and of the "new" corrected series presented in Table 1.

Fig. 2. Patrón estacional (promedios mensuales a largo plazo 1953-84) de la serie "antigua" de la componente del esfuerzo del viento a lo largo de la costa reportada por Bakun (1987) y la "nueva" serie corregida presentada en la Tabla 1.

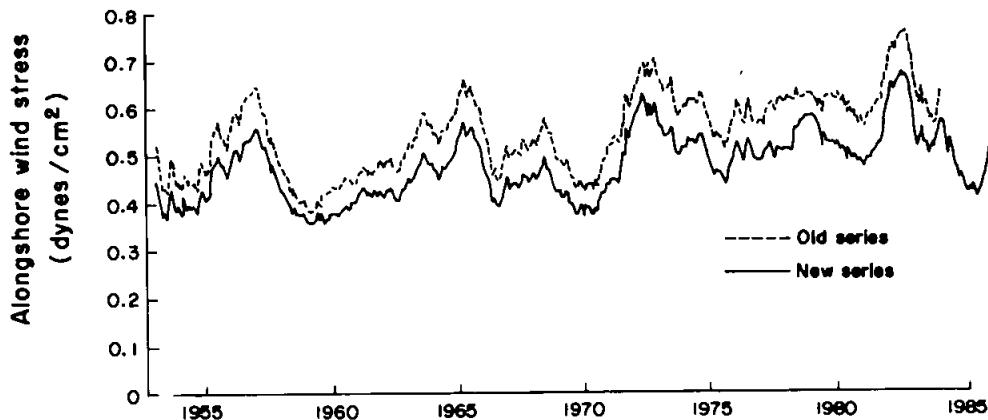

Fig. 3. Low-frequency nonseasonal variations: 12-month running means of monthly time series values of the "old" monthly series (dashed line) of alongshore component of wind stress reported by Bakun (1987) and the "new" corrected series (solid line) presented in Table 1.

Fig. 3. Variaciones de baja frecuencia no estacionales: promedios móviles de 12 meses de los valores de la "antigua" serie mensual (línea punteada) de la componente del esfuerzo del viento a lo largo de la costa, reportada por Bakun (1987) y la "nueva" serie corregida (línea sólida) presentada en la Tabla 1.

appropriate 1953-84 long term monthly mean from each monthly value, yields $r = .962$ and $b = 1.12$. Removing the seasonal variation and the long term linear trend by "12th-differencing" each series (subtracting from each value the value for the same month one year earlier) yields $r = .953$ and $b = 1.09$. The regression line directly intersects the origin (intercept = 0.00) in all three cases.

Bohle-Carbonell (this volume), in examining the fractal dimensions of several series related to the anchoveta fisheries, uses the Bakun (1987) series. As discussed in Mendelsohn (this vol.), there is a close relationship between fractal dimension and fractal differencing in time series. Statistical estimates of the fractional differencing parameter d are determined from properties of the observed and theoretical spectrum. As the "old" and "new" series have similar spectra, there should be little change in these estimates, and the use of the "new" series should not affect Bohle-Carbonell's conclusions. (In fact, the estimate of fractional differencing for the "old" series is $d = .2212$, while for the "new" series it is $d = .2857$, see Mendelsohn (this vol.) for details).

Cury and Roy (1989) estimate optimal environmental windows for the Peruvian anchoveta, as well as for species from other eastern boundary current regions, using a turbulence index (wind speed cubed) as the environmental variable. Their study is unaffected by this correction, as they use the Trujillo series of Mendo et al. (1987). It is expected that other studies that may have used the earlier series will be similarly unaffected to any substantial degree.

Abstract

Seasonally-averaged estimates of zooplankton volume (in ml/m³) for the northern, central and southern part of the Peru coast (up to about 170 km offshore) are presented, based on 6,658 hauls with a Hansen net of 0.33 m² mouth area. Highest zooplankton biomasses occur in spring (October-December) in all three zones. Overall, zooplankton abundances are lowest off central Peru. There is a clear declining trend of zooplankton biomasses from the mid-1960s to the mid-1980s. The impact of various El Niño events on zooplankton abundance and composition is briefly discussed.

Resumen

Se presentan las variaciones estacionales, promedio de los volúmenes de zooplancton (en ml/m³) para el área norte, centro y sur de la costa peruana (dentro de 170 km de la costa). Esta contribución se basa en 6,658 muestrados colectados con red Hensen de 0.33 m² de área de boca.

Las biomassas de zooplancton mas altas se presentan en la estación de Primavera (Octubre-Diciembre) en las tres zonas investigadas. En general estos volúmenes son menores en el área central del Perú. Entre la década del 60 a la década de 80 se observa una clara tendencia decreciente de los valores del zooplancton.

El impacto de diferentes eventos El Niño sobre abundancia y composición del zooplancton son discutidos.

Introduction

This contribution presents a time series, covering the years 1964 to 1987, of zooplankton volumes off Peru and attempts to identify some of the causes for the observed changes.

During the initial period covered by this time series (1974-1969), only two mild El Niño events occurred (1965, 1969); thus, one may use this period as reference for the general pattern of zooplankton distribution off Peru. Subsequent El Niño events, notably that of 1982-1983, altered this pattern and reduced overall abundances (Carrasco and Santander 1988). The present contribution provides previously unpublished background material on these changes.

Materials and Methods

The basic material consists of 6,658 samples collected during research and survey cruises of the *Eureka* type, carried out by IMARPE from 1964 to 1987.

Samples were obtained from vertical hauls between a depth of 50 m and the sea surface, using a Hensen net of 0.33 m² mouth area and 300 µ mesh, and then fixed in 10% formaldehyde buffered with Borax.

Large coelenterates were removed by filtration (using mesh sizes of approximately 1 cm) prior to all zooplankton analyses. Then the fish eggs and larvae were set aside and the volume of the remaining zooplankters was determined using the displacement method (Kramer et al. 1972). All values are expressed in ml/m³.

The sampling area (Fig. 1) covers the Peruvian coastline from 3°30'S to 18°30'S, and up to 170 km off the coast. Considering the characteristics of its fish populations and its oceanographic attributes, the Peruvian Coast has been divided into three zones:

Area "A" (03°30'-05°59'S), strongly influenced by equatorial surface waters (mainly in spring and summer). The coastal zone is also subjected to mixing processes during summer.

Area "B" (06°00'-13°59'S), wherein a widening of the shelf is observed, and with an upwelling area north of 09° S and another off Callao (12° S). The country's main pelagic fisheries are localized in this area.

Area "C" (14°00'-18°30'S), characterized by intense upwelling (Zuta and Guillén 1970) and high biological productivity (phytoplankton, zooplankton).

As data collection was not continuous, the zooplankton volumes obtained have been averaged by seasons: summer (January-March), autumn (April-June), winter (July-September) and spring (October-December).

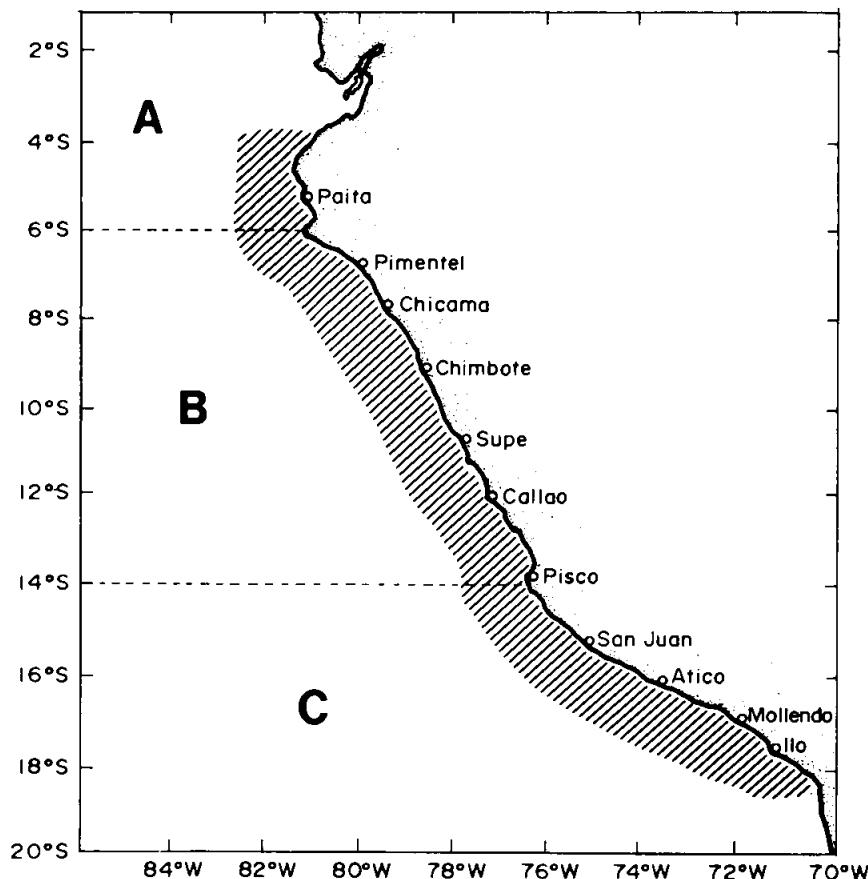

Fig. 1. Definition of sampling areas: A (3°30'-5°59'S), B (6°-13°59'S) and C (14°-18°30'S) off Peru. Seaward extension of sampling area is about 170 km on the average.

Results and Discussion

The zooplankton volumes, averaged by season, are presented in Table 1. In general, it can be seen that the volumes are higher during spring (see Fig. 2).

Comparatively, Area "A" ($03^{\circ}30' - 05^{\circ}59'S$) presents the highest zooplankton volumes, a fact attributable to the influence in this area of equatorial surface water, which carries larger zooplanktonic organisms than the cold water of the coastal current.

The other matter to highlight with regard to these series is the notable reduction of the zooplankton volumes along the Peruvian coast, very evident since the El Niño event of 1972-1973. Volumes for the period 1972-1987 represent, on the average, around 30-40% of those observed for previous years (Fig. 3).

Carrasco and Santander (1988) pointed out that during the 1983 El Niño and for the area of $060^{\circ}-120^{\circ}S$, copepod abundance decreased to 1/6 with respect to 1977 and 1981, and that generally, zooplankton volumes decreased drastically.

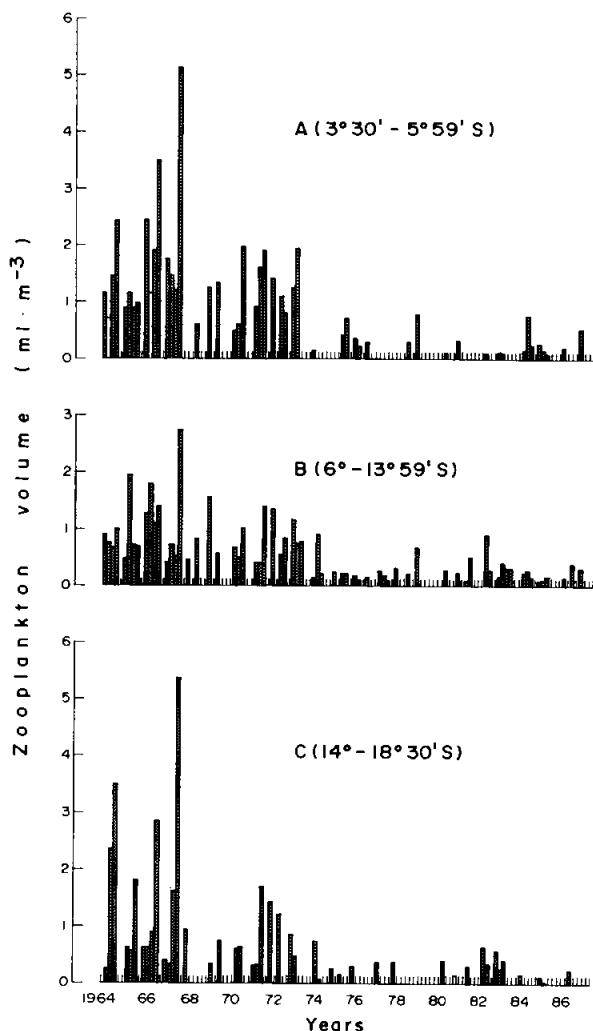

Fig. 3. Trend of zooplankton abundance off Peru, 1964 to 1987. Note strong decline in all three zones and overall lower biomasses in area B.
 Fig. 3. Tendencia de la abundancia del zooplancton en el Perú, 1964 a 1987. Notar la fuerte disminución de la biomasa en las tres zonas y los valores más bajos en área B.

The observed decline of zooplankton volumes, assuming that it reflects a real decrease of zooplankton biomass, is probably related to the observed changes in the southeastern Pacific ecosystem - coincidental with the 1972-1973 El Niño - which led to a drastic decrease of the anchoveta stock and to the associated increase of other species, such as sardine, horse mackerel and mackerel (Zuta et al. 1983).

These changes in the ecosystem would have generated a greater zooplankton consumption by these predator species. Muck and Sanchez (1987) showed that the contribution of anchoveta to the diet of horse mackerel *Trachurus murphyi* and mackerel (*Scomber japonicus*) decreased during the 1976-1982 period. Also, the results of stomach content analyses presented in Muck (this vol.) suggest a switch from anchoveta to a zooplankton diet for both predators after 1980. Hence, it is reasonable to assume that there has been a greater zooplankton contribution to the diet of horse mackerel and mackerel during this period, leading to a decline of zooplankton biomasses.

Abstract

The diet and morphological parameters (mouth width, gut length, eye pigmentation and mouth function) of larval anchoveta (*Engraulis ringens*) and sardine (*Sardinops sagax*) of the Peruvian upwelling system were studied, based on samples obtained in February/March 1982. The relationships body length/mouth width and body length/gut length show significant differences: an anchoveta has a larger mouth than a sardine of the same size but a shorter gut; the two species also differ in a number of morphological characteristics. Species and size composition of prey in the guts of first feeding larvae (anchoveta: 3-3.5 mm; sardine: 4-4.5 mm) are significantly different: the former feeds almost exclusively on a pure phytoplankton diet (phytoflagellates, dinoflagellates; 30 µm width) whilst the latter feeds almost exclusively on zooplankton (copepod eggs and nauplii; 70 µm width).

These findings for first feeding larvae suggest a high larval mortality for anchoveta during El Niño periods when primary production is reduced drastically; they also agree with the hypothesis that differences in larval mortality during El Niño events are one of the decisive factors for the transition from anchoveta to sardine in the Peruvian upwelling system.

For older anchoveta and sardine larvae (>5.5 mm), there is a wide diet overlap for all stages of calanoid copepods, and phytoplankton becomes less important as an energy source.

Resumen

Se estudia la dieta y los parámetros morfológicos (ancho de boca, longitud de intestino, pigmentación de ojo, y función de la boca) de las larvas de anchoveta (*Engraulis ringens*) y sardina (*Sardinops sagax*) del sistema de afloramiento peruano, basados en muestras obtenidas en febrero/marzo de 1982. Las relaciones del cuerpo longitud/ancho de boca, longitud del cuerpo/longitud de intestino, muestran diferencias significativas: una anchoveta tiene la boca mas larga que una sardina de la misma talla, pero un intestino corto; las dos especies también difieren en un número de características morfológicas. La composición de tamaño de presas y de especies en los intestinos de la primera alimentación larval (anchoveta: 3-3.5 mm; sardina: 4-4.5 mm) son significativamente diferentes: las anchovetas se alimentan casi exclusivamente de una dieta pura de fitoplancton (fitoflagelados, dinoflagelados: 30 µm de ancho) mientras que las sardinas se alimentan casi exclusivamente de zoopláncton (huevos de copépodos y nauplios: 70 µm de ancho).

*PROCOPA Contribution No. 23. (An earlier version of this paper was presented at the International Symposium on the Larval History of Fishes, 8th Annual Larval Conference, Vancouver, Canada, 6-10 May 1984).

Estos resultados de la primera alimentación de larvas sugieren una alta mortalidad larval para la anchoveta durante períodos de El Niño cuando la producción primaria se reduce drásticamente. Ellos también concuerdan con la hipótesis de que las diferencias en la mortalidad larval durante los eventos de El Niño sea uno de los factores decisivos en la transición de anchoveta a sardina en el sistema de aforamiento peruano. Para las anchovetas viejas y larvas de sardina (> 5.5 mm) hay un amplio traslape de dietas para todos los estadios de copépodos calanoides y el fitopláncton es menos importante como fuente de energía.

Introduction

Survival rate during the larval stage of fishes has been suggested for over 70 years (Hjort 1914) to be a decisive factor controlling recruitment and thus the population density of stocks.

Studies on clupeoid fish larvae show that early stages can only survive approximately 1.5-3.5 days without food (Lasker et al. 1970; Houde 1974, 1978; Rojas de Mendiola and Gómez 1980). This period, however, becomes much shortened when water temperatures become abnormally high, as was the case in the upper 70 m of the Peruvian upwelling system during the "El Niño" event of 1982-1983, when temperatures of 26-30°C were reached (Villavicencio and Muck 1983). Therefore, the chances of survival of the individual larval stages appear to be largely dependent on strategy and efficiency of food uptake (May 1974). This applies in particular to the first larval stages following the absorption of the yolk sac, whose feeding success is often extremely poor (Braum 1967; Rosenthal and Hempel 1970; Blaxter and Staines 1971; Hunter 1972).

The aim of this study is to identify the food niches and feeding strategies of anchoveta (*Engraulis ringens*) and sardine larvae (*Sardinops sagax*) by gut content analysis as well as through the comparison of morphological parameters. This study follows up on contributions on the feeding behavior of *E. ringens* larvae by Rojas de Mendiola (1974, 1980) and Ware et al. (1981).

As sardine and anchoveta have widely overlapping distribution areas off Peru, the results will be discussed with respect to food competition and to environmental changes such as caused by El Niño events.

Materials and Methods

Larvae were sampled during day and night at 45 stations along the Peruvian coast ($18^{\circ}04'S$ to $3^{\circ}23'S$) during February and March 1982 by vertical hauls (50-0 m) of a Hensen net (0.33 m² mouth area; 300 µm mesh size). The larvae were preserved in ethanol (70%) and later analyzed at the Instituto del Mar del Peru (IMARPE) with respect to (i) standard length, gut length, mouth width, (ii) eye pigmentation, (iii) mouth function and (iv) diet composition.

The mouth of the preserved larvae was assumed to be functional either when it was found open, or when it could straightforwardly be teased open. Fully pigmented eyes were considered functional.

Diet organisms were removed from the gut, identified, counted and grouped into 37 size classes of 10 µm intervals by measuring the short axis of the food particles, the important parameter limiting food ingestion.

Diet composition was described by reporting the percent frequency of occurrence (F(%)) of the diet items by taxa, stage and/or size class and the percentage of the total number of diet items (N(%)). As an index of the relative importance of each diet item the product of F% and N% (Laroche 1982; Govoni et al. 1983) has been used.

The calorific content of various items was estimated from the equation

$$\log_{10}\text{cal.} = -9.416 + 3.026\log_{10}\text{width} \quad \dots 1)$$

(width in µm; r = 0.95) derived from data in Theilacker and Dorsey (1980) for phyto- and zooplankton species, including different size classes of nauplii and copepodites.

Equation (1) was used to estimate (i) the importance of phytoplankton in the gut compared to zooplankton and (ii) to estimate optimum prey widths, defined as the size class in a group of food organisms representing the fraction with the highest calorific value in the gut of each larva.

Results and Discussion

Size of First Feeding Larvae

As shown in Table 1, the minimum size for anchoveta with food in the gut was 3.02 mm and for sardine 4.07 mm. These findings agree with the available data on mouth and eye function in Fig. 1 which show curves obtained by grouping 1,077 anchoveta larvae ranging from 2 to 5 mm and 106 sardine larvae ranging from 3.5 to 5 mm into six size classes of 0.5 mm width. For both species, there is a close linkage between eye and mouth functions: larvae with completely pigmented eyes also had an open mouth. This development starts for anchoveta at around 2.7 mm, and is completed at a length of ca. 4 mm. In sardine, this development starts below 4 mm and is completed with 5 mm.

Diel Feeding Activity

The diel feeding cycle of anchoveta and sardine larvae is shown on Fig. 2. Grouping the available data (points) in four-hour intervals and computing means led to the solid line for anchoveta and the dotted one for sardine. The lines suggest nocturnal feeding by anchoveta (as in adults, see Pauly et al., this vol.) and a more diurnal feeding behavior in sardine. However, the available data points are widely scattered and more data are needed to decide whether or not species-specific differences do occur.

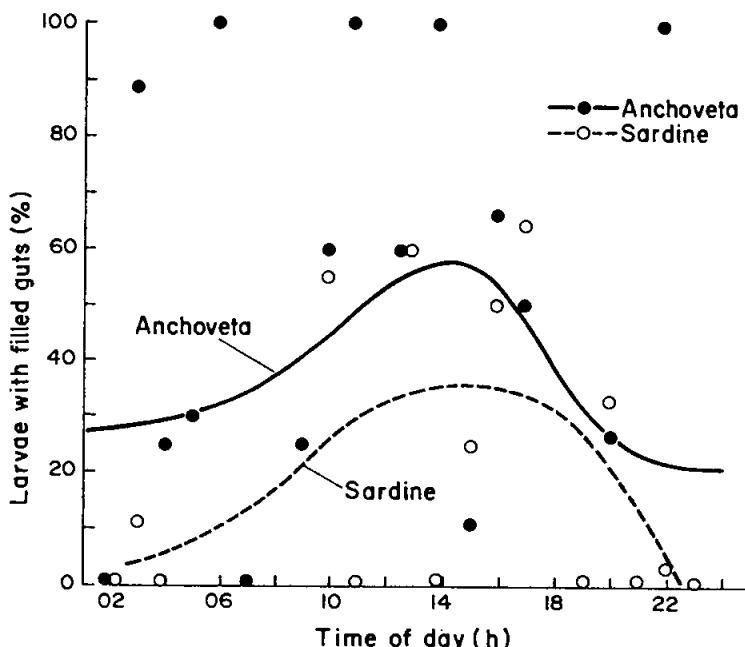

Fig. 2. Data on the diel feeding activity of anchoveta and sardine larvae. Dots: observations; lines: fitted by eye to 4-hourly means. Note suggestion of nocturnal feeding in anchoveta and of diurnal feeding in sardine larvae.

Notar la sugerencia de una alimentación nocturna y de una alimentación diurna en las larvas de anchoveta y sardina, respectivamente.

Diet Composition

Table 2 lists the diet organisms and their frequencies as estimated by gut analysis. The highest values for the relative importance of a diet item ($N(\%) \times F(\%)$) correspond, in the case of anchoveta, to copepod nauplii (45-135 μm), to phytoflagellates (5-15 μm) and to copepod eggs (45-75 μm). In the case of sardine, the highest values of $N(\%) \times F(\%)$ pertain to nauplii (45-135 μm), copepod eggs (47-75 μm) and adult copepods (115-345 μm).

Related to the total number of diet groups analyzed, the fraction of copepods (including their eggs) is higher in sardine (92.2%) than in anchoveta larvae (46.2%). In contrast, we found algae in 53% of the cases in anchoveta and in only 6% in sardine.

Feeding Strategies

The clear differences presented above in the diet composition of both species are caused mainly by the different feeding behavior of the first-feeding larvae. Of the anchoveta larvae between 3.0 and 3.5 mm, 77% feed exclusively on phytoplankton, mainly flagellates with a

mean width of $29.6 \mu\text{m} \pm 25.3$, whilst the first feeding larvae of sardine (4.0-4.5 mm) had all ingested nauplii, with a mean width of $72.1 \mu\text{m} \pm 16.6$ (Table 3).

With increasing length, anchoveta larvae gradually shift towards a zooplankton diet. The shift from phyto- to zooplankton starts at a standard length of ca. 4 mm. In contrast to this, sardine larvae of all size classes are strongly specialized and have an almost pure zooplankton diet; the average for the "mixed" and phytoplankton fraction is less than 10%.

In only 10 of the 45 hauls did the two species co-occur, with a total of 161 anchoveta and 175 sardine larvae. Co-occurrence occurred from $5^{\circ}15'$ to $15^{\circ}00'$. Analysis of these data is difficult due to the low number of larvae with food in their guts (25% in anchoveta, 29% in sardine). Nevertheless, a comparison of their diet composition showed the same tendency (Table 3): almost exclusive feeding on zooplankton by sardine larvae whilst about 50% of the anchoveta diet is mixed food and pure phytoplankton:

The mean total calorific gut content for different larval size classes, for samples collected 5° and 20°S , mainly around 13° (Table 4), was calculated using equation (1) to identify possible differences in feeding efficiency. The results suggest no differences for larvae >5 mm but

differences of a factor of 5 for larvae in the 4-5 mm size class. These differences are most probably caused by the low feeding success of first-feeding sardine larvae.

To quantify the importance of phytoplankton as food resource from a bio-energetic viewpoint, equation (1) has been used to estimate the total calorific content of the phytoplankton fraction in the gut of each larva as a percentage of total calorific content (=100%). These values were averaged for the individuals of each size class (Table 4) and plotted (Fig. 3).

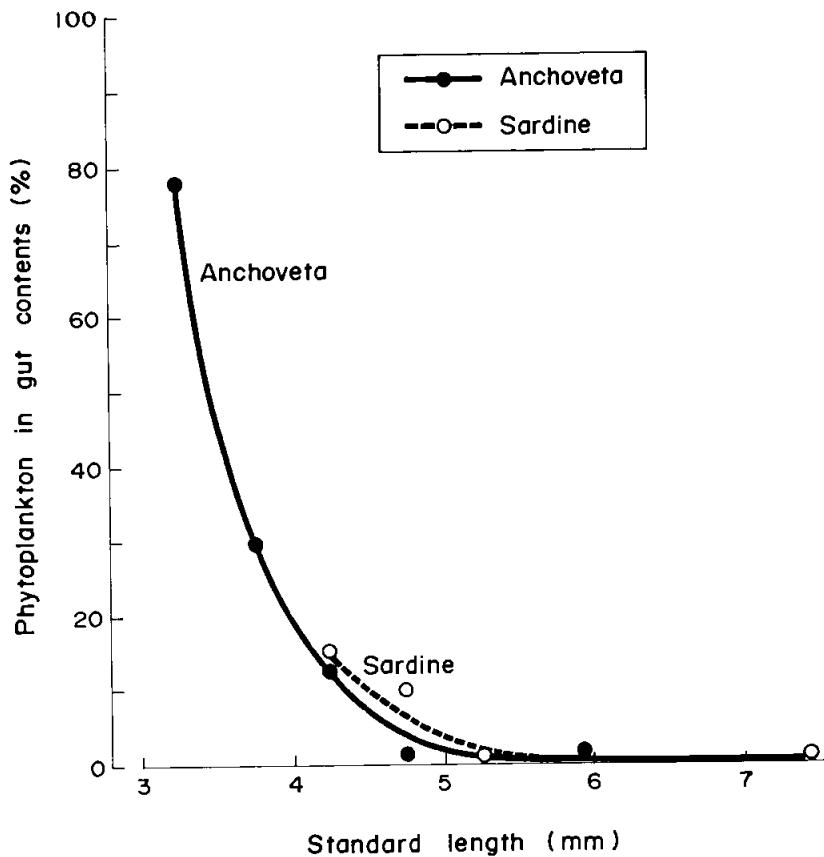

Fig. 3. Contribution of phytoplankton (in % of the gut contents, in cal.) in the diet of larval anchoveta and sardine.

Fig. 3. Contribución de fitoplacton (en % del contenido intestinal, en calorías) en la dieta de las larvas de anchoveta y sardina.

First feeding larvae of anchoveta mainly use phytoplankton (80%) as an energy resource. Phytoplankton, however, becomes negligible when the anchoveta larvae are larger than ca. 4.5 mm. For sardine, phytoplankton is of little importance (16%) for the youngest larvae and tends towards zero in larvae larger than 5 mm.

Regression and Correlation Analyses

The results of the regression and correlation analyses of morphological and functional characteristics are given in Table 5.

The relationships standard length/gut length and standard length/mouth width are significantly different between species: an anchoveta of 10 mm has a shorter gut (5.99 vs. 7.03 mm) but a wider mouth (0.65 vs. 0.60 mm) than a sardine larva of the same standard length.

For the relationships length/minimum, prey width, length/maximum prey width and length/optimum prey width, positive correlations were found for both species. These were associated, however, with low values of the correlation coefficient (r). Therefore, species-specific differences cannot be derived using the available data set. An exception seems to be the

| | sardine | 76 | 4.07-16.0 | 0.08 | - | - | - | 44.4 |

^aOnly the last relationship (sardine larval length vs. optimum prey width) was not significant (at 95% level).

^bFour types of equations were tested in each case (linear, exponential, logarithmic and power function); those reported here gave the best fit.

length/minimum prey width relationship. For anchoveta, the minimum size of the ingested food particles increases with increasing larval length, while for sardines, there is a weak negative relationship.

Fig. 4 presents the results of Table 5 to allow comparison of the specific difference on the interrelationships between larval length, mouth width and particle size.

Discussion

Overall, the analysis of the available gut content data is hindered by the relatively low number of larvae with food in the gut. With respect to the daytime hauls, this seems to be more a question of sampling technique than of larval feeding behavior. Stress often induces defecation in fish larvae and probably a vertical haul from a depth of 50 m is sufficient to trigger off the defecation process. Therefore a gentler treatment such as using MOCNESS surface tows (Govoni et al. 1983) would be a more adequate technique.

Comparably low number of larvae with food in their guts were reported for *Engraulis mordax*, *Sardinops sagax* and *Limanda ferruginea* (Arthur 1976; Smith et al. 1978).

The most important result based on the data sampled in February/March 1982 is undoubtedly that anchoveta larvae in their first feeding period are almost exclusively phytophagous whilst the first feeding sardine larvae are mainly zoophagous.

Additional data from a cruise conducted in September 1982 show a similar tendency with respect to the anchovy phytoplankton diet for larvae smaller than 4 mm (n=30): 37% pure phytoplankton, 33% mixed diet, 30% pure zooplankton.

This food niche separation of the early larval stages corresponds to field data about distribution and environmental conditions. Rojas de Mendiola and Ochoa (1980) reported a strong correlation between phytoplankton abundance and the spawning centers of adult *Engraulis ringens*. Similar findings were reported by Walsh et al. (1980).

In contrast to anchoveta, sardine spawn relatively far offshore (35-70 km off the Peruvian coast, see Santander and de Castillo 1977) where zooplankton is more abundant than inshore (Walsh et al. 1980).

Even where both species co-occurred for a given size class, a higher percentage of anchoveta larvae had a pure phytoplankton or a mixed diet in the guts than did sardine larvae.

Because there is almost no overlap of the food niches of first-feeding anchoveta and sardine larvae, their survival rates will be different in periods of low phytoplankton availability, such as during El Niño events (Guillen and Rondan 1974; Guillen 1983) or when there is a southward displacement of the spawning stock to less productive areas (Walsh 1978; Walsh et al. 1980). Spawning in the sardine appears to occur earlier during El Niño years (Walsh et al. 1980). However, even if spawning in both species were to occur at the same time, sardine larvae would have a higher chance of survival during the initial phase of an El Niño event because of the time lag between reduced primary production and decreased zooplankton biomass. But with respect to the El Niño event of 1982-1983, which was probably the strongest since the beginning of this century, larvae of both species did not appear to have any chance of survival when hatched during the peak of this event (January-March 1983): compared with values based on normal years (Rojas de Mendiola 1981; Rojas de Mendiola et al. 1983), total planktonic biomass decreased by an average factor of 15 along all of the Peruvian coast and the temperature in the upper 70 m reached values between 26 and 30°C (Villavicencio and Muck 1985). Using a larval feeding and growth model (P. Muck, unpublished data) for *E. ringens* and *S. sagax*, Villavicencio and Muck (1985) estimated survival to be zero for both larvae during the peak of the 1982-1983 El Niño event.

Walsh et al. (1980) state that the high larval mortality of anchoveta, caused by the poor food conditions during the El Niño of 1965, 1972 and 1976, together with overfishing of the adult population, were the main reasons for the collapse of the Peruvian anchoveta stock and the partial replacement of anchoveta by sardine.

Niche separation for first feeding larvae is not directly related to difference in mouth width. Zoophagous sardine larvae of 4 mm feed on items with a mean particle width of 0.07 mm and have a mouth width of 0.23 mm. Phytophagous anchoveta larvae of 3 mm, on the other hand, which feed on items with a mean particle width of 0.03 mm have a mouth width of 0.24 mm.

The fact that sardine larvae have a longer gut than anchoveta of the same size does not appear to be of much ecological relevance because the gut diameter of sardine is smaller than that of anchoveta and thus the entire gut volume is more or less the same (B. Rojas de Mendiola, pers. obs.).

Fig. 4 suggests a second food niche separation for larvae larger than 9 mm. However, the correlation coefficients associated with the regression equations are low and the wide confidence limits for the regression coefficients (Table 5) prevent firm conclusions to be drawn.

With increasing length of anchoveta larvae, their mean maximum prey width and mean minimum prey width increase. This is also the case with the relationship length/optimum prey width, defined as the size of the group of diet organisms with the highest calorific value (see above). These findings correspond to those of optimal foraging theory (Eggers 1976), which implies a switch to larger food particles with increasing body size. This also agrees with the findings of Rojas de Mendiola (1981) on *E. ringens* and with data on other marine fish larvae (*Sardinops sagax* and *Engraulis mordax*, Arthur 1976; *Sardinops sagax*, Herrera and Balbontin 1983; *Leiostomus xanthurus* and *Micropogonias undulatus*, Govoni et al. 1983). Hunter (1977) found similarly that, when larval Californian anchovy *E. mordax* are fed exclusively with dinoflagellate *Gymnodinium splendens* (a mean width of 50 µm), growth becomes asymptotic at about 6 mm. Vlymen (1977) predicted similar results based on a feeding/growth model of Californian anchovy.

Using the formula for the length/minimum prey width relationship (Table 5) identical results are obtained: a 6 mm, growing anchoveta larvae consumes organisms not smaller than 60 µm (mean minimum particle size).

The relationship length/minimum prey width for sardine shows a weak downward trend, similar to what has been reported in the literature for larvae of *Brevoortia patronus* (Govoni et al. 1983), *Trachurus japonicus* and *Scomber* spp. (Yokota et al. 1961).

Thus overall, our results show a good agreement with those of other researchers working on various clupeoid and other species of pelagic fishes.

Abstract

A brief review of past research on the food and feeding habits of the Peruvian anchoveta (*Engraulis ringens*) is presented, with emphasis on studies published by the author and her collaborators. The methods used in these studies are recalled and an appended database is introduced, consisting of 3,682 records of individual anchoveta stomach contents, sampled from November 1953 to August 1974 and providing full details as to sampling location, time and hour, size, sex, maturity stages and other ancillary variables.

Resumen

Se presenta una breve revisión de las investigaciones realizadas sobre el alimento y hábitos alimenticios de la anchoveta peruana (*Engraulis ringens*) dando énfasis a los estudios publicados por el autor y sus colaboradores. Se mencionan nuevamente los métodos utilizados en estos estudios y se anexa una base de datos que provee información individual sobre el análisis del contenido estomacal de 3,682 anchovetas muestreadas desde Noviembre de 1953 a Agosto de 1974, e incluye además datos en detalles sobre localidad de muestreo, fecha, hora de colección, sexo, madurez sexual, longitud de las anchovetas, peso y otras variables.

Introduction

The Peruvian anchoveta *Engraulis ringen* (Jenyns) supported for many years the largest single-species fishery of the world, and its population biomass estimates ranged between 20 and 30 million tonnes (Longhurst 1971).

It is unarguably the high phyto- and zooplankton production of the Peruvian upwelling system which made such stock sizes possible. Besides, being extremely fecund, anchoveta are able to switch easily from phyto- to zooplankton, and from filtering to particulate feeding. This ability to switch between trophic levels in relation to environmental conditions is certainly one of the reasons for the persistence of this species in its highly variable environment. Schaefer (1965) correctly pointed out, however, that the high abundance of anchoveta off Peru is primarily a result of its predominantly phytophagous habits.

The feeding adaptations of anchoveta cannot totally prevent it from being negatively affected by environmental fluctuations. In fact, as noted by Frost (1974) the fishes of pelagic ecosystems tend to be strongly affected by fluctuations of the lower elements of the food web. Changes of species and size composition of their food organisms not only have a strong impact on the survival and individual and population growth of pelagic fishes, but also induce change in the geographic location of the stocks themselves.

Outside of the spawning season, the Peruvian anchoveta is generally concentrated at an average distance of 75 km from the coast, which is where phytoplankton concentrations are

*Present address: 7488 Andorra Place, Boca Raton, Florida 33433, USA.

highest (Rojas de Mendiola 1981). Spawning occurs closer to the coast, in colder waters (Santander 1981).

Rojas de Mendiola and Gómez (1981) stressed that certain phytoplankton species are of great importance for anchoveta, i.e., that this herbivore does not feed on whatever happens to be in the water. Rather, anchoveta largely select the phytoplankton species they consume. Conversely, different kinds of phytoplankton affect the development and growth of anchoveta differently.

Thus, for example in November 1975, in conjunction with the first stage of the El Niño event of 1976, a change occurred in the composition of the phytoplankton along the northern coast of Peru, which resulted in very high abundance of the dinoflagellate *Gymnodinium splendens*, normally not a food item of adult anchoveta (but see Muck et al., this vol., with regard to larval anchoveta). In May and June 1976, *G. splendens* had produced widespread blooms. Tsukayama and Alvarez (1981), unsurprisingly, reported a decline of the growth rate of anchoveta during the 1976 spring seasons: specimens of 15 months of age had reached only 12.5 cm and weights almost 30% less than normal. They attributed this to a scarcity of appropriate food items and/or to a reduction of their quality.

The behavior of anchoveta varies widely between day and night. Johannesson and Vilchez (1981) demonstrated how schools, formed in daytime, dissolve at night and how the fish move into deeper water. Mathisen (this vol.) related such daily migration to the feeding behavior of anchoveta.

It is thus obvious that food and feeding are among the most important factors affecting and/or regulating fish populations. Consequently, different purposes can be achieved from the analysis of fish stomach samples: they can be used to obtain general information on a food chain, on competition between species, on seasonal habitat changes, etc. Also geographical differences of feeding can be studied, and related to differences of growth rate, abundance, migration patterns, etc. Thus, in fishes, food and feeding habits studies can contribute to elucidating the causes of variations of stock abundances in space and time.

The first information on the food and feeding habits of anchoveta to become available were published by Vogt (1940), Sears (1941) in Peru, and Schneider (1943), Mann (1954) and de Buen (1958) in Chile.

This author began her studies of the food and feeding habits of the Peruvian anchoveta in the early 1950s (Rojas 1953), and the bulk of her further studies were reported in Rojas de Mendiola (1959, 1966, 1969, 1971, 1973, 1974, 1979, 1981), Rojas de Mendiola and Gómez (1981), Rojas de Mendiola and Ochoa (1973, 1981), Rojas de Mendiola et al. (1969), Ware et al. (1981) and Muck et al. (this vol.). The key points that emerged from these studies are as follows:

- the food and feeding habits of anchoveta change with length in relation to changing physiological requirements. Anchoveta larvae ingest round diatoms which do not form chains, and dinoflagellate such as *Gymnodinium splendens* (see Muck et al., this vol.). Postlarval anchoveta feed on zooplankton and prefer copepod eggs and nauplii. Juvenile anchoveta are largely zooplanktivorous, while the adults - at least off central and northern Peru - are almost exclusively phytoplanktivorous;
- with regard to adult food preference, distinct latitudinal differences are apparent. Anchoveta from the south of Peru and the north of Chile feed almost exclusively on zooplankton while those of the north are phytoplanktivorous. These latitudinal differences are matched by related differences in branchiospine number, length and spacing and relative gut length (see Palomares et al., 1987), as well as by different vertebral counts. This suggests the existence of at least two different stocks along the southeastern Pacific coast;
- changes in environmental conditions such as the El Niño events of 1972-1973 greatly alter the distribution patterns of the two anchoveta stocks. Thus, the reduction of suitable phytoplankton in the north of Peru led to the almost total disappearance of anchoveta in that area, and the few that were encountered had empty stomachs, or had ingested euphausiids. In the south of Peru, on the other hand, anchoveta were found which had relatively long guts, a large number of gill rakers and their stomachs full of phytoplankton, suggesting that a north-south migration had taken place;

- during such environmental changes, cannibalism appears to increase, wherein both eggs and larvae are ingested in larger amounts than during other periods (for example, a single anchoveta of 16 cm had ingested at least one hundred eighty 15-mm larvae).

The overwhelming majority of the contributions which led to these generalizations were, however, descriptive studies, which do not provide the type of quantitative information needed, e.g., for modelling purposes.

This paper makes available to a wider scientific community the bulk of the raw data, covering the years 1953 to 1974, upon which earlier studies were based. Together with the data of Alamo (this vol.), covering the years 1974 to 1982, these data can be used to answer questions such as:

- i) have the quantity and the quality of the food of the Peruvian anchoveta changed in the last decades?
- ii) if such changes occurred, can they be related to changes of (a) individual, (b) population growth rates and (c) the maturation and reproduction of anchoveta?
- iii) what is the extent of food size selection by anchoveta; e.g., does anchoveta consume the larger or the smaller representatives of the phyto- and zooplankton?
- iv) if anchoveta become particulate feeders and concentrate on zooplankton when appropriate phytoplankton is scarce, does it imply a greater consumption of anchoveta eggs and larvae and does this impact on subsequent recruitment?
- v) are there one or several populations of anchoveta, and if the latter applies, are they distinguishable by their food and feeding habits?

It is likely that answers to at least some of these questions, and of other related questions that may be formulated, will be obtained from detailed analysis of the data presented below.

Materials and Methods

Sources of Samples

The material presented here stems from different sources and were collected from 19 November 1953 to 8 August 1974. The anchoveta samples of 1953 and early 1954 were obtained on board Danish vessels especially contracted by the "Compañía Administradora del Guano", which needed basic information on anchoveta, the major food item of the guano birds (see Tovar 1987 and Muck and Pauly 1987 for an account of their biology). From mid-1954 to 1958, the principal source of samples was the reduction (i.e., fish meal) plants, especially those in the Chimbote area (see Castillo and Mendo 1987 for an account of anchoveta meal production). From 1960 to 1975, samples were obtained from a number of sources, notably scientific and "EUREKA" surveys organized by the Instituto de Investigación de Recursos Marinos (IREMAR) and its successor, the Instituto del Mar del Perú (IMARPE). Some samples were also obtained during this period by foreign scientific vessels operating in Peruvian waters.

Analytical Procedures (General)

The anchoveta samples generally consisted of about 100 specimens, taken randomly from the catch. They were immediately put into a plastic bag, into which a 20% formalin-seawater solution was poured such as to entirely cover the anchoveta sample and to stop all further digestion process. A label with details on the sample was then put into each bag. This label included the following information: date and hour of sampling, location (or fishing area, see Fig. 1), depth (if more than 16 fathoms) and sea surface temperature (in °C). Whenever possible, a plankton sample was also taken, using a net with a 75 µm mesh size.

Upon working up those samples, it emerged after about one year that within-sample differences of stomach content weight and composition were rather small. It was therefore decided to take at random subsamples of 20 specimens from the original samples of 100 anchoveta.

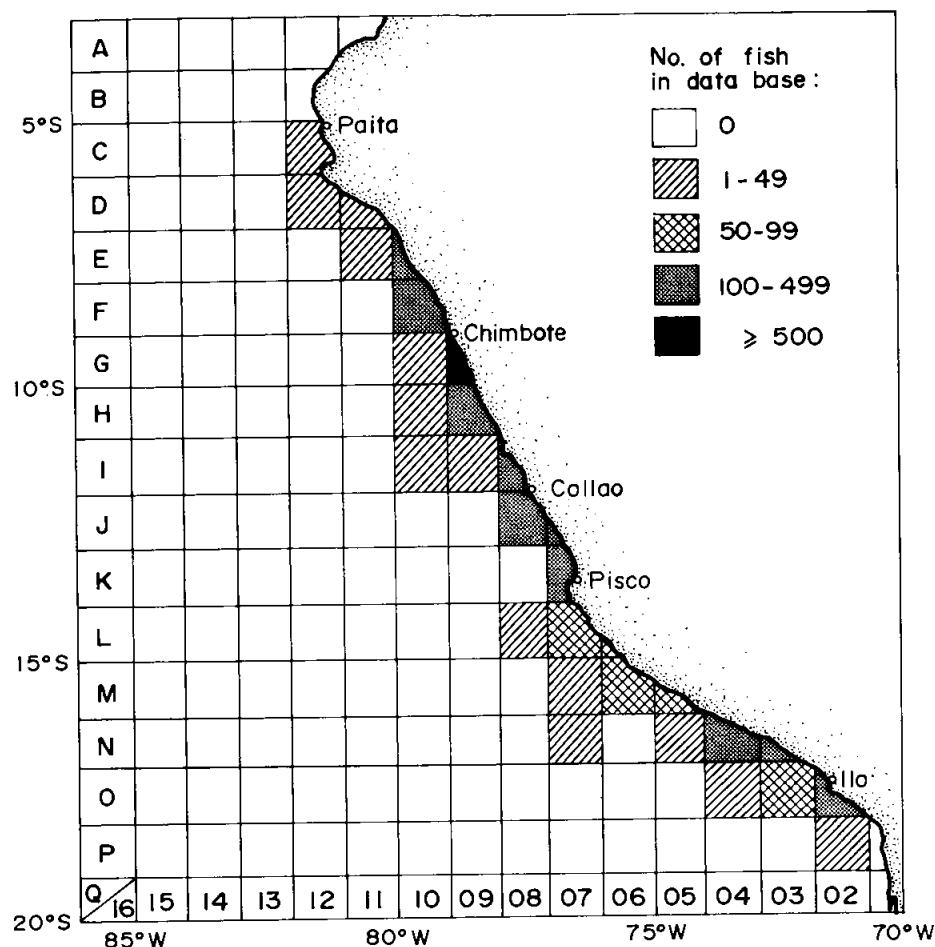

Fig. 1. Sampling location and density of data included in database described in text. Letters and numbers refer to the code used by the author to locate samples along the Peruvian coast.

Fig. 1. Lugar de muestreo y densidad de los datos incluidos en la base de datos que se describe en el texto. Las letras y los números indican el código usado por el autor para localizar los muestreos a lo largo de la costa peruana.

In the laboratory, the following information were recorded for each intact individual anchoveta:

- i) total and/or standard length (in mm)
- ii) total wet weight (in g).

The body cavity was then opened and the following were recorded:

- iii) sex and sexual maturity
- iv) stomach fullness and stomach contents.

Details on the various procedures of scales used for items (iii) and (iv) are given below.

Recording of Reproduction-Related Information

The scale in Table 1, adapted from Clark (1954) and Einarsson et al. (1966), was used to describe the various maturation stages of the sampled anchoveta.

Table 1. Maturity scale for anchoveta, adapted from Clark (1954) and Einarsson et al. (1966).^a
Tabla 1. Escala de madurez para la anchoveta, adaptada de Clark (1954) y Einarsson et al. (1966).

| Stage | Definition |
|-----------------|-----------------------------------|
| I | Immature <8 cm TL |
| II | Immature or recuperating ≥8 cm TL |
| III | Maturing; prespawning phase |
| IV ^b | Mature; spawning phase |
| V ^c | Partially spent |
| VI ^c | Spent; postspawning |

^aEditors' note: this scale was derived at a time when anchoveta and other clupeoids were assumed to spawn only once or twice during a spawning season. The recent finding that anchoveta and other clupeoids may spawn once a week during the spawning season (see Lasker 1985) does not detract from the utility of the older scale as a descriptive tool (see other contributions in this vol.).

^bMaturity stage IV is used at IMARPE to separate the adult from the juvenile stock (see also Pauly and Soriano 1987).

^cColor differences are used to differentiate stages V and VI.

Recording of Food and Feeding-Related Information

The digestive tract of each anchoveta was removed, and gently extended. Its length was then measured (in mm, from the pylorus to the anus).

Then, the stomachs (gastric and pyloric parts) were separated from the rest of the gut, and weighted (to the nearest mg). Their degree of fullness was then determined according to the scale in Table 2.

Table 2. Scale used for quantifying the fullness of anchoveta stomachs.
Tabla 2. Escala utilizada para cuantificar la llenura de los estómagos de anchoveta.

| Fullness | Original definition | Percent fullness ^a |
|--|---------------------------------|-------------------------------|
| full ("lleno" or "repleto") | Stomach is full and distended | 100 |
| almost full ("semilleno" or "mesolleno") | Stomach is more than 70% full | 60 |
| almost empty ("semivacio" or "poco") | Food fills up to 30% of stomach | 40 |
| empty ("vacio") | Stomach is empty | 0 |

^aSee Pauly et al. (this vol.) for details on the derivation of this new scale, which was also used for the contents of the pyloric parts of the stomachs (see text).

The stomachs were then cut open, their contents separated from the stomach walls and added to flasks partly filled with 10% formalin solution. The empty stomachs were weighed and the weight of the stomach contents determined by subtraction. The state of digestion of the stomach contents was then assessed, using the scale in Table 3.

Table 3. Scale used for quantifying the state of digestion of anchoveta food organisms.

Tabla 3. Escala usada para cuantificar el estado de digestión de los organismos en el contenido estomacal de las anchovetas.

| State | Definition | Corresponding percentage ^a |
|---|---|---------------------------------------|
| whole ("entero") | organisms intact | 100 |
| almost whole ("casi entero") | organisms almost intact | 70 |
| halfdigested ("semidigerido" or "semientero") | organisms broken into parts but still easily identifiable | 50 |
| almost digested ("casi digerido") | only parts of organisms are identifiable | 25 |
| digested ("digerido") | food contents consists of a paste and/or organisms are totally unidentifiable | 0 |

^aEditors' note: assumed values, used to allow some quantitative analysis of what originally were qualitative data.

Until 1958, stomach contents were routinely identified and reported at the species level. For phytoplankton, all identification and counts were based on an aliquot, drawn from the thoroughly mixed material of each stomach sample. For zooplankton, the entire samples were counted, with each still identifiable head providing a count of one. All identifications were performed with a compound microscope. This type of detailed analysis was replaced, starting in 1959 and in the early 1960s by a less detailed analysis, i.e., all identifications were still performed at the species level, but without counting the single cells of aliquots or the individual zooplankton in the whole sample. Rather, a qualitative scale was used, as follows:

- +++ very abundant
- ++ abundant
- + present

Fish eggs and fish larvae were always counted; the identification of the anchoveta eggs was facilitated by their rather unique elliptical shape.

Finally, the whole stomach sample was put into a Petri dish, and the overall ratio of phyto- to zooplankton was assessed subjectively, using a stereomicroscope.

Tabulation and Computerization of Results

Tabulation of the information described above occurred in three major phases:

- i) initial tabulation on raw data sheet (by the author and her associates), including counts or relative abundance of all taxa identified as food items. This process occurred from 1953 to 1974 and formed the basis for the author's various publications on anchoveta food and feeding habits, listed above;
- ii) retabulation in 1987 by the author of a large fraction of the data in (i) reduced as follows:
 - a) only 1/5 of all fish from each sample were taken (at random), such as to reduce the number of fish collected at the same place, date and hour;
 - b) only the 4 or 5 most abundant food items reported from each stomach were included (the overall list of items still includes over 259 entries, see Pauly et al., this vol.)
- iii) creation, in 1988, at ICLARM, of a computerized database including the data in (ii) and those of Alamo (this vol.). This part of the work was performed by Ms. Susan "Tuttay" Luna working under the supervision of Dr. D. Pauly and using the DBase III Plus program implemented on an IBM XT-compatible microcomputer. Finally, Ms. Astrid Jarre performed quality and logic checks on the entries.

Results and Discussion

The database reported upon here includes data on 3,682 specimens of anchoveta, sampled from 11 November 1953 to 8 August 1974. Fig. 1 illustrates the spatial distribution of these 3,682 specimens along the Peruvian coast, as well as the code used to record the sampling locations.

Further details on the contents and organization of this database, which also includes the anchoveta stomach content data of Alamo (this vol.) may be found in Appendix I of this volume.

A very preliminary analysis of some aspects of this database is presented in Pauly et al. (this vol.). Readers are welcome to probe further.

Acknowledgements

The author would like to take this opportunity to thank her collaborators, notably former coauthors for their cooperation over several decades of work on the food of the Peruvian anchoveta. Sincere gratitude also goes to GTZ/PROCOPA for support of the work leading to this contribution, to Dr. D. Pauly for his translation and editing of the original Spanish-language draft and to Ms. S. Luna and Ms. A. Jarre for their assistance with the computerized version of the database presented here.

Abstract

A database on anchoveta (*Engraulis ringens*) stomach contents covering the period from 3 September 1974 to 18 October 1982 is presented which complements a similar database initiated in 1953 by B. Rojas de Mendiola. Most of the available 6,053 individual records include information on sampling location and time (date and hour), length, weight, gonad weight and maturity stage, as well as on food and feeding (stomach contents in weight and by taxa). Some ancillary information and a brief review of the sampling methods are provided.

Resumen

Se presenta la base de datos sobre contenidos estomacales de anchoveta (*Engraulis ringens*) que abarca el período del 3 de Septiembre de 1974 al 18 de Octubre de 1982 como complemento a la base de datos iniciados en 1953 por B. Rojas de Mendiola. La mayoría de los 6,053 registros individuales incluyen información sobre área y tiempo del muestreo (fecha y hora), longitud, peso, peso de gonada y estadio de madurez, así como alimento (peso de contenido estomacal por grupo taxonómico). Se incluye una breve información complementaria y una breve revisión sobre los métodos de muestreo.

Introduction

The large fluctuations of abundance of Peruvian marine fish stock have prompted a series of investigations aimed at explaining these changes in terms of the peculiarities of the Peruvian upwelling system.

Food and feeding habits studies form a significant part of these investigations. Rojas de Mendiola (this vol.) gives a brief review of such work with regard to the anchoveta (*Engraulis ringens*).

These previous studies and that of Alamo (1981) indicate that anchoveta is a planktivore which relies, as shown on Fig. 1, on both phytoplankton (e.g., diatoms) and zooplankton (e.g., copepods) and that its diet varies with size, maturity stage, area, season, water temperature, etc. Particularly important are the facts that anchoveta also consume fish eggs and larvae - including its own - and that such cannibalism (and predation with reference to the other species) can be assumed to have a strong impact on stock sizes (Santander et al. 1983).

Detailed analysis of the database accumulated so far, however, cannot proceed without the data being computerized and should not proceed without reference to the related database of Rojas de Mendiola (this vol.).

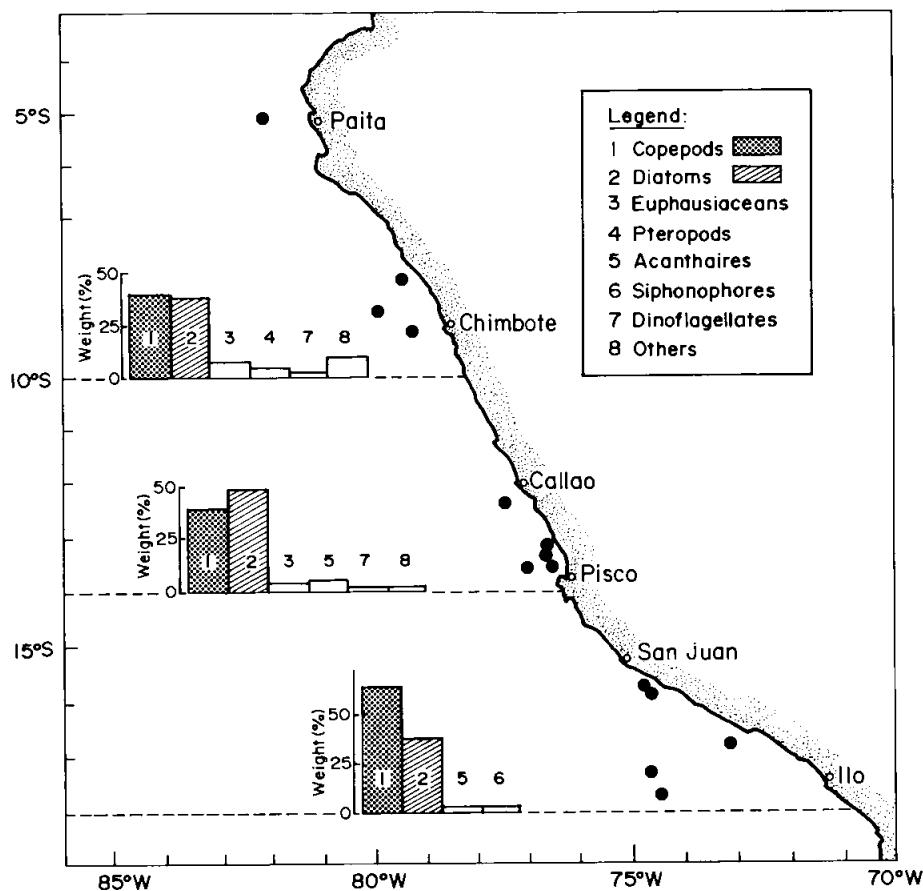

Fig. 1. Food composition of 500 anchoveta sampled in September 1982, during the 1982-1983 El Niño event. (Black dots represent sampling stations; redrawn from Sánchez de Benites et al. 1985).

Fig. 1. Composición del alimento de 500 anchovetas muestreadas en Septiembre de 1982, durante el evento El Niño 1982-1983 (los puntos negros representan las estaciones muestreadas; redibujado de Sánchez de Benites et al. 1985).

Materials and Methods

Sampling Procedures

The data presented here were collected from 3 September 1974 to 18 October 1982, and consist of records for 6,053 specimens of juvenile and adult anchoveta caught off Peru between 4 and 18°S.

All fish samples were preserved in 10% formalin and the sampling data and hour were recorded. Sampling locations were reported as 1° Marsden squares (during computerization, the Marsden square numbers were replaced by the longitude and latitude corresponding to the center of each square, see Fig. 2), and the sea surface temperature noted.

Overall, sampling procedures resembled those of Rojas de Mendiola (this vol.).

Analytical Procedures

In the laboratory the specimens of each anchoveta sample were analyzed individually, and the following information noted:

- i) total length (in cm),
- ii) total wet weight (in g),
- iii) sex and maturity stage,
- iv) amount of visceral fat,
- v) stomach content weight (in g),

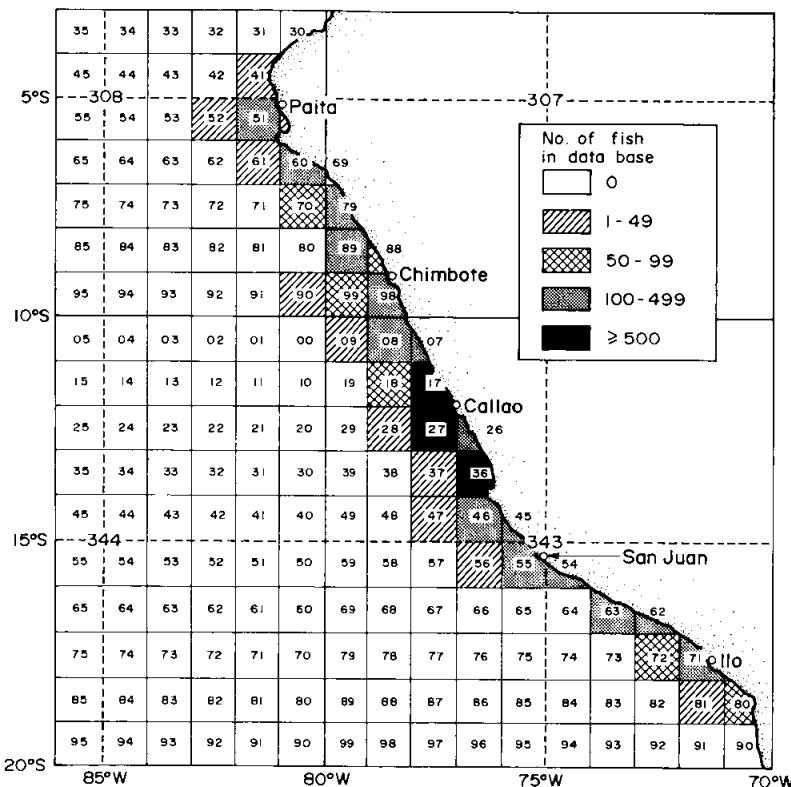

Fig. 2. Distributions of individual anchoveta sampled along the Peruvian coast, as included in the database discussed here. The numbers refer to Marsden squares, used for initial coding of the origin of anchoveta samples. [Note that all fish caught within a given square were attributed the longitude and latitude of the center of that square (for example, square #307/99 = 9°30'S and 79°30'W)].

Fig. 2. Distribución de anchovetas muestreadas a lo largo de la costa peruana, incluidas en la base de datos discutidos en este trabajo. Los números se refieren a cuadrados Marsden usados en las muestras originales de anchoveta. [Notar que, todos los peces capturados dentro de un cuadrado fueron atribuidos a la longitud y latitud del centro del cuadrado (ejemplo, cuadrado #307/99 = 9°30'S y 79°30'W)].

- vi) stomach fullness,
- vii) state of digestion, and
- viii) relative abundance of food items.

The scale used to assess maturity stages was the same as that of Rojas de Mendiola (this vol.); Table 1 was used to assess the amount of visceral fat present in each anchoveta.

The anchoveta stomach contents were separated into their phytoplanktonic and zooplanktonic components by means of a 130 μm filter. The identification of zooplankton organisms was performed with a grooved "Bogorov" counting tray (Newell and Newell 1963) and a stereomicroscope.

The phytoplankters were identified from a drop of the stomach content sample using a microscope; their relative abundance was expressed through the following scale:

- +++ very abundant
- ++ abundant
- + present

The fullness of anchoveta stomachs and the state of digestion of the various food items were assessed using scales presented in Rojas de Mendiola (this vol.).

Results and Discussion

This contribution serves as a background for a database and not as a presentation and analysis of available information.

An example of the type of analysis that could be conducted with this database is the strong association of various taxa occurring in anchoveta stomach contents with different water temperature ranges.

Table 1. Scale used for rapid visual assessment of the amount of visceral fat in anchoveta.^a
 Tabla 1. Escala usada para la evaluación visual rápida de la grasa visceral en anchoveta.

| Stage | Definition |
|-------|---|
| 0 | no fat is visible along digestive tract |
| 1 | only a thin thread of fat is visible along intestine |
| 2 | visceral fat is abundant but does not entirely surround intestine |
| 3 | intestine is entirely surrounded by fat |

^aEditors' note: this scale corresponds to that developed by Johan Hjort for herring (see Suworow 1959, p. 427 and Nikolsky 1963, p. 211). A Spanish version is given in Tresierra and Culquichicón (1982).

Thus, diatoms are generally associated with low temperatures, and this often involves the genera *Asterionella*, *Chaetoceros*, *Coscinodiscus*, *Rhizosolenia*, *Thalassionema* and *Thalassiosira*, among others.

Conversely, dinoflagellates tend to be associated with high temperatures and this often involves the genera *Ceratium* and *Peridinium*.

Other groups - particularly zooplankters such as *Calanus*, *Eucalanus*, *Oncea*, *Centrophages* or Euphausids are common at various temperature regimes, while anchoveta eggs occur mainly in spawning areas during the spawning seasons, and thus can help defining these in the absence of other information.

Details on the contents and organization of the database presented here, and which can be used to answer such questions are provided in Appendix I of this volume.

A very preliminary analysis of some aspects of this database is presented in Pauly et al. (this vol.). Readers are welcome to probe further.

Acknowledgements

Many thanks to Ms. Marilú Bouchon for assisting with the initial tabulation of raw data, to Ms. M.L. "Deng" Palomares and Ms. Susan "Tuttay" Luna for their help in converting my handwritten tables into the computerized database reported upon here, to Ms. Astrid Jarre for performing quality and logic checks on the database and to Dr. D. Pauly for his translation and editing of the original Spanish-language draft.

Abstract

This contribution presents the results of a first analysis of a computerized database on the food and feeding habits of the Peruvian anchoveta (*Engraulis ringens*) for the years 1953 to 1982, besides serving as (partial) documentation for the same database, which documents, on an unaggregated basis, nearly 10,000 anchoveta stomach contents and ancillary information. Detailed phylogenetic "trees" were graphed whose "branches" represent different food items and whose frequency of occurrence is reported. The diel periodicity of mean stomach contents in over 5,000 anchoveta was used to estimate their food consumption. Feeding starts near noon and is continuous until near midnight. A ration of $0.45 \text{ g} \cdot \text{day}^{-1}$ (mixed phyto- and zooplankton) was estimated from anchoveta with a mean live weight of 20.4 g. This implies, given a mean total mortality of $Z = 4.5 \text{ year}^{-1}$, a relative population consumption rate of 3.3%/day. The fraction of zooplankton in the mixed phyto- and zooplankton diet of anchoveta was found to increase with distance from the coast, southern latitude and temperature.

Resumen

En esta contribución se presentan los resultados de un primer análisis de la base de datos computarizada sobre el alimento y hábitos alimenticios de la anchoveta peruana (*Engraulis ringens*) para los años 1953 a 1982, los que además sirven como documentación (parcial) para la misma base de datos, cuyos documentos sobre una base desagregada, llegan casi a los 10,000 contenidos estomacales de anchoveta y adicional información. Se grafican "árboles" filogenéticos cuyas "ramas" representan los diferentes ítems alimentarios y cuya frecuencia de ocurrencia es reportada. La alimentación comienza cerca del medio día y se continúa hasta cerca de la medianoche. Para estimar el consumo de alimento se utilizó la periodicidad diaria del contenido estomacal promedio de más de 5,000 anchovetas. Se estimó una ración de $0.45 \text{ g} \cdot \text{día}^{-1}$ (mezcla de fito- y zooplancton) para anchovetas de un peso promedio de 20.4 g. Esto significa que, dado un promedio de mortalidad de la población de $Z = 4.5 \text{ año}^{-1}$, la tasa de consumo de la población es de 3.3%/día. La fracción de zooplancton en una dieta mixta de fito- y zooplancton se incrementa con la distancia de la costa, con la latitud hacia el sur y con la temperatura.

Introduction

This contribution presents a preliminary analysis of the food types and food consumption of the Peruvian anchoveta (*Engraulis ringens*), based on the data of Rojas de Mendiola (this vol.) and Alamo (this vol.), covering the years 1953 to 1982. No attempt will be made here to extract all information contained in the now computerized Rojas/Alamo database. Rather we aim at providing a framework for future, more detailed studies on the feeding habits of anchoveta in relation to fluctuations of the Peruvian upwelling system.

This contribution consists of three parts:

- i) presentation and partial reduction of the taxonomic diversity of anchoveta food items;
- ii) testing of some extant hypotheses on the spatial and temporal variations of the zooplankton fraction (ZF), i.e., the ratio zooplankton/(zooplankton + phytoplankton) in anchoveta stomach contents; and
- iii) estimation of the daily ration of an "average" anchoveta and of the relative food consumption of the entire population.

Part (i) serves three purposes: (a) to illustrate the wide range and the frequency of occurrence of food items recorded from anchoveta stomachs, (b) to identify the taxonomic affinities of these food items and (c) to assign these food items to a small number of taxonomically homogeneous groups, such as needed for future quantitative analyses.

The hypotheses involved in Part (ii) are: (a) that anchoveta in the north of Peru have lower ZF values than those in the south, (b) that anchoveta sampled inshore should have a lower ZF than anchoveta sampled offshore (Vinogradov 1981), (c) that high sea surface temperatures (SST) are associated with higher ZF and (d) that anchoveta in the 1950s and 1960s had higher ZF than in the following decades (Palomares et al. 1987).

Finally, we shall present in Part (iii) the first rigorous attempt to estimate the daily ration of anchoveta based on stomach content data. Our aim here is to allow comparison with and a calibration of ration estimates based on metabolic considerations (Villavicencio 1981; Tsukayama and Sanchez 1981; Palomares et al. 1987), and eventually, to allow quantitative modelling of the transfer of primary production off Peru (Chávez et al., this vol.; Mendo et al., this vol.) to higher trophic levels.

For general orientation, we present a photo of an anchoveta (Fig. 1.) and, in Figs. 2, 3 and Table 1, some key anatomical features of anchoveta that are related to food capture and processing.

Tabla 1. Información seleccionada sobre el trato digestivo de la anchoveta *Engraulis ringens*.

| Item | Measurement | Mean value | Mean in % of S.L. |
|---------------------|--|------------|-------------------|
| Standard length | from tip of snout to end of hypural bone | 108 | 100 |
| Height | maximum height of fish between dorsal and ventral edge of body | 20.0 | 18.5 |
| Width | maximum width of fish | 12.5 | 11.6 |
| Visceral cavity | length of visceral cavity | 43.2 | 40.0 |
| "Branchial gut" | from tip of snout to begin of esophagus | 30.5 | 28.2 |
| "Foregut" | from begin of esophagus to begin of stomach (bulge) | 16.5 | 15.3 |
| Stomach | from begin of stomach to pylorus | 12.0 | 11.1 |
| Intestine | from pylorus to anus | 125 | 116 |
| All digestive tract | from tip of snout to anus | 184 | 170 |

^a Adapted from Harder (1960), based on three specimens collected near Guanape, Peru, in 1954, by staff of the Inter-American Tropical Tuna Commission; all lengths are in mm.

Materials and Methods

The data used for Part (i) of this contribution are the raw data sheets of Rojas de Mendiola (this vol.) and Alamo (this vol.), which include, for each anchoveta sampled, up to six of the most abundant food items. Each of these food items was listed, and the total number of occurrences was recorded (no distinction was made between the periods covered by the data of Rojas de Mendiola, this vol., and those of Alamo, this vol.). Then, the taxonomic affinities of each item were identified, using standard references (e.g., Bougis 1976; Mann 1978 or Barnes 1980) and phylogenetic "trees" were constructed which included only organisms recorded as anchoveta food item. Finally, fifteen groups of food items were defined, whose boundaries represent compromises between taxonomic homogeneity and the need for a roughly similar number of occurrences within each group.

Part (ii) is based on analysis of the ZF values in the Rojas/Alamo database. Fig. 4 presents the geographic distribution of entries in this database, as well as definitions for:

- (a) the northern, central and southern sections of the Peruvian coast (all locations north of $9^{\circ}59'S$, $10^{\circ}00' - 13^{\circ}59'S$ and all locations south of $14^{\circ}00'S$, respectively), and
- (b) the inshore, intermediate and offshore parts of the coastal strip inhabited by anchoveta.

With regard to hypotheses (c) and (d) above, the three temperature ranges selected are <17 , ≥ 17 to ≤ 19.9 and $\geq 20^{\circ}\text{C}$, while the three periods considered are 1953 to 1974, 1975 to 1978 and 1979 to 1985. The cutoff points used for hypotheses (a) to (d) were selected such as to allow enough entries to be represented in each of the three groups used for the comparisons, and also such as to be consistent with an earlier subdivision (that between northern, central and southern anchoveta stock and/or substock, pertaining to hypothesis (a)). All analyses involving ZF values were performed after application of an arcsine transform, which has the effect of normalizing percentage values (Sokal and Rohlf 1981; Sachs 1984), a fact which we confirmed for the data at hand. Differences in mean transformed ZF values were tested for significance using t-tests (Sachs 1984).

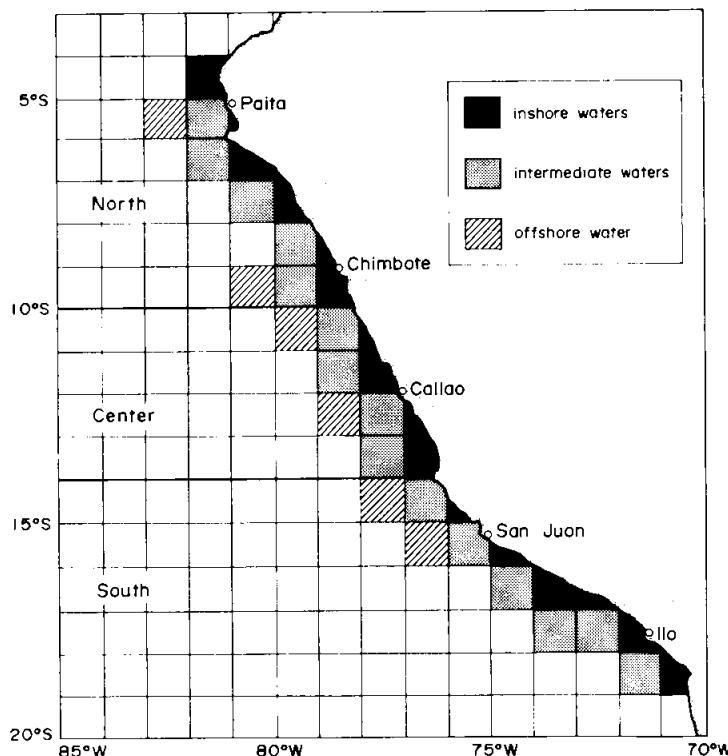

Fig. 4. Definition of the southern, central and northern zone of the Peruvian coast, and of inshore, intermediate and offshore waters as used in this contribution. All shaded squares contain anchoveta samples (see text).

Fig. 4. Delimitacion de las zonas Sur, Centro y Norte de la costa peruana; y de las aguas costeras, intermedias y afuera de la costa, como se presentan en esta contribución. De todos los cuadros sombreados se obtuvieron muestras de anchoveta (ver texto).

Part (iii) of this contribution was performed in a number of steps best presented jointly, then discussed separately in more detail:

- (1) Establishment of a quantitative relationship between degrees of fullness and relative stomach content weight in those anchoveta for which both types of entries were available;
- (2) Estimation of relative stomach content weight using the relationship above in all anchoveta for which only the degree of fullness was available, and transformation of absolute weight of stomach content into relative weight of stomach content in all anchoveta for which both stomach content weight and body weight were available;
- (3) Computation of mean relative weight of stomach content of anchoveta caught in different parts of a 24-hour cycle; and
- (4) Application of the model of Sainsbury (1986) for estimation of daily ration from the data in (3).

The scale expressing degree of stomach fullness used by Rojas de Mendiola (this vol.) and Alamo (this vol.) has four steps: "empty", "half empty", "half full" and "full". Two of these are straightforwardly reexpressed as % values: "empty" = 0% and "full" = 100%. Rojas de Mendiola's definition of "half empty" differs from that of "half full", however, and these two categories could therefore not be set equal to each other and to 50%.

We have, therefore, used an iterative approach, i.e., identified the % value for "half empty" (and hence also the % value of "half full" = 100 - half empty) which maximized the correlation between (transformed) relative stomach weight and degree of fullness. Also, we have estimated the parameter b in the relationship:

$$\sqrt{\frac{(\text{stomach content weight}) * 100}{\text{body weight}}} = b * (\%) \text{ fullness} \quad \dots 1)$$

where the square root transformation was used to normalize the variance (the corresponding linear regression had an intercept not significantly different from zero, hence the reduced form of equation (1)).

Once the optimal % values for "half empty" and "half full" and the corresponding version of equation (1) were identified, relative stomach content weights ($S_{(R)}$) were derived for all anchoveta for which only fullness values had been available and a file was created which also included $S_{(R)}$ values computed directly from weight of stomach content/body weight data pairs.

To describe a diurnal cycle of mean stomach content weights, the available $S_{(R)}$ values were then grouped into 16 classes of 1.5 h each, i.e., 00h01' - 01h30' (mid-point 00h45'), 01h31' - 03h00' (mid-point 02h15'), etc. These groupings appear optimal given the relatively low number of nighttime observations, and the need to use an appropriate number of classes, i.e., between about 12 and 20 (Sokal and Rohlf 1981).

In view of the non-normal distribution of the $S_{(R)}$ values within each temporal class, we abstained from using the arithmetic mean as a measure of central tendency. Rather, we used

$$\bar{X} \approx 0.33 (D_1 + \tilde{X} + D_9) \quad \dots 2)$$

where D_1 and D_9 are the 1st and the 9th deciles, respectively, and \tilde{X} the median, i.e., the 5th decile (Sachs 1984). The corresponding estimate of standard deviation is

$$\text{s.d.} \approx 0.39 (D_9 - D_1) \quad \dots 3)$$

Standard errors (s.e.) were computed from

$$\text{s.e.} = \text{s.d.} * \sqrt{n} \quad \dots 4)$$

The model used here for the estimation of food consumption (i.e., daily ration, or R_d) from the diurnal dynamics of stomach contents is the simpler of two models presented by Sainsbury (1986).

The model assumes that the 24-hour diurnal cycle can be split into two phases:

- (a) a feeding phase, during which feeding occurs at a constant *rate*, while a constant *fraction* (*c*) of the stomach content is (simultaneously) being evacuated, and
- (b) a nonfeeding phase, during which only stomach evacuation takes place.

If, for a 24-hour cycle

τ is the "physiological time," measured from the beginning of feeding period (in hour),
 S_τ the mean weight of the stomach content at time τ ,
 α the feeding rate (in $\text{g} \cdot \text{hour}^{-1}$),
 c the evacuation rate (in hour^{-1}),
 T_m the duration (in hour) of the feeding period, and
 S_r the residual stomach content at the beginning of feeding period,

then the mean weight of stomach content can be calculated as

$$S_\tau = \frac{\alpha}{c} + \frac{(cS_r - \alpha)}{c} e^{-c\tau} \quad \dots 5a)$$

during feeding time when $0 < \tau < T_m$, and

$$S_\tau = \left[\frac{\alpha}{c} + \frac{(cS_r - \alpha)}{c} e^{-cT_m} \right] e^{-c(\tau - T_m)} \quad \dots 5b)$$

during nonfeeding time when $T_m < \tau < 24$ hours,

wherein

$$S_r = \frac{\alpha(e^{-c(24h-T_m)} - e^{-c*24h})}{c(1-e^{-c*24h})} \quad \dots 5c)$$

The daily ration of food consumed is calculated as $R_d = \alpha T_m$.

Fitting of equation (5) to our data was performed after smoothing the data over three time intervals, using a BASIC program implemented on an MS-DOS computer^a, and representing a modified version of a FORTRAN listing kindly supplied by Dr. K. Sainsbury (CSIRO, Hobart, Australia, pers. comm.)

Estimation of the gross food conversion efficiency of anchoveta (K_1 = growth increment/food ingested, see Ivlev 1966) was based on the equation

$$K_1 = (dw/dt)/R_d \quad \dots 6)$$

with growth increment (= growth rate) obtained from

$$dw/dt = 3KW ((W_\infty/W)^{1/3} - 1) \quad \dots 7)$$

^a Available from the first author.

i.e., from the first derivative of the von Bertalanffy Growth Function (VBGF). The VBGF has, for growth in weight the form

$$W_t = W_{\infty} (1 - e^{-K(t-t_0)})^3 \quad \dots 8)$$

where W_t is the weight at age t
 W_{∞} the asymptotic weight
 K a growth constant, and
 t_0 the "age" at weight zero.

The estimate of K_1 was then used to estimate the parameter β in the equation:

$$K_1 = 1 - (W/W_{\infty})^{\beta} \quad \dots 9)$$

through

$$\beta = \log_{10} (1 - K_1) / \log_{10} (W/W_{\infty}) \quad \dots 10)$$

Using β and K , food consumption (Q) per unit biomass (B) of an age-structured population (Q/B) can be estimated using a simplified version of the model of Pauly (1986), of the form

$$Q/B = \frac{\int_0^{\infty} \frac{(dw/dt) e^{-Z(t-t_0)}}{K_1(t)} dt}{\int_0^{\infty} W_t e^{-Z(t-t_0)} dt} \quad \dots 11)$$

where $K_{1(t)}$ is the gross conversion efficiency as a function of fish age (obtained by combining equations (8) and (9)), Z is the exponential rate of total mortality in the population studied, and W_t is obtained from equation (8).

Transfer efficiency (E_t) was obtained, finally, from $E_t = Z * (B/Q)$, i.e., by multiplying the inverse of the relative food consumption by the production biomass ratio (because $Z = P/B$ under steady-state conditions, see Allen 1971).

Results and Discussion

Figs. 5 and 6 present taxonomic "trees" of anchoveta food items listed in the raw data sheets of B. Rojas de Mendiola and A. Alamo, along with number of occurrences. Figs. 7 to 9 provide details on three important "branches" of these trees, the Protozoa (with emphasis on the dinoflagellates), the Chrysophyta (i.e., the diatoms), and the crustaceans (with emphasis on the copepods). Altogether 259 different food items were identified, from nearly 10,000 individual anchoveta, and this number would have been far greater had it not been for the fact that only the 5-6 most abundant food items were recorded from each stomach examined.

An approach is presented in Table 2 to arrange these food items into 15 more or less homogeneous groups with roughly comparable numbers of occurrences (ratio of smallest to largest = 1:27, i.e., 1.43 log units). Of these 15 groups, 14 are used for the food type fields (I-V) in the computerized database of Rojas de Mendiola (this vol.) and Alamo (this vol.). (The 15th group, i.e., anchoveta eggs, is listed separately, see below.) Table 3 gives details on the "miscellaneous items" of Table 2.

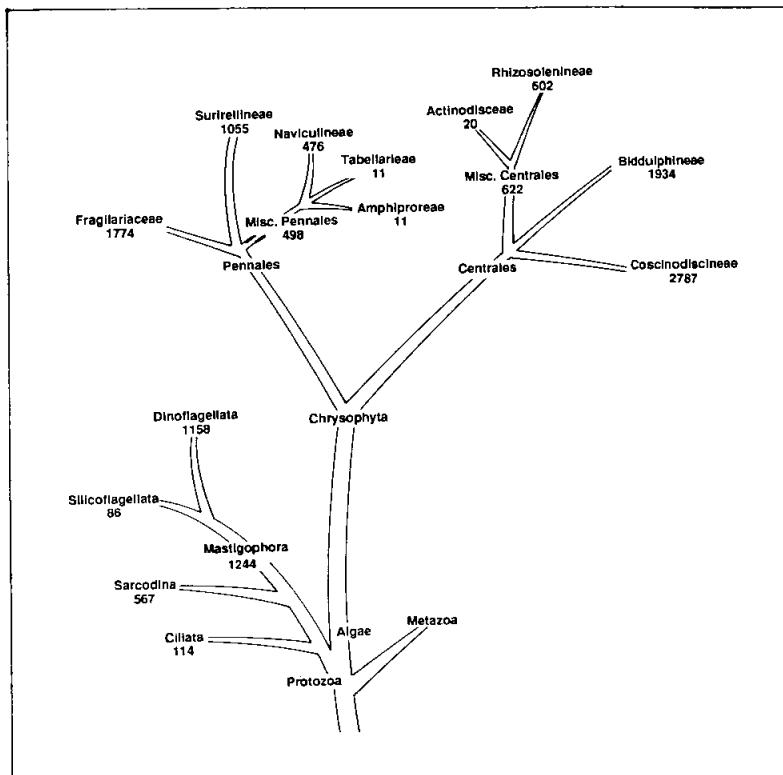

Fig. 5. Taxonomic "tree" for single cell organisms ingested by Peruvian anchoveta, 1953 to 1982 (numbers indicate occurrences; see also Fig. 6).

Fig. 5. Diagrama taxonómico (posición genealógica) de los organismos unicelulares ingeridos por la anchoveta, 1953 a 1982. (Los números indican la ocurrencia; ver también Fig. 6).

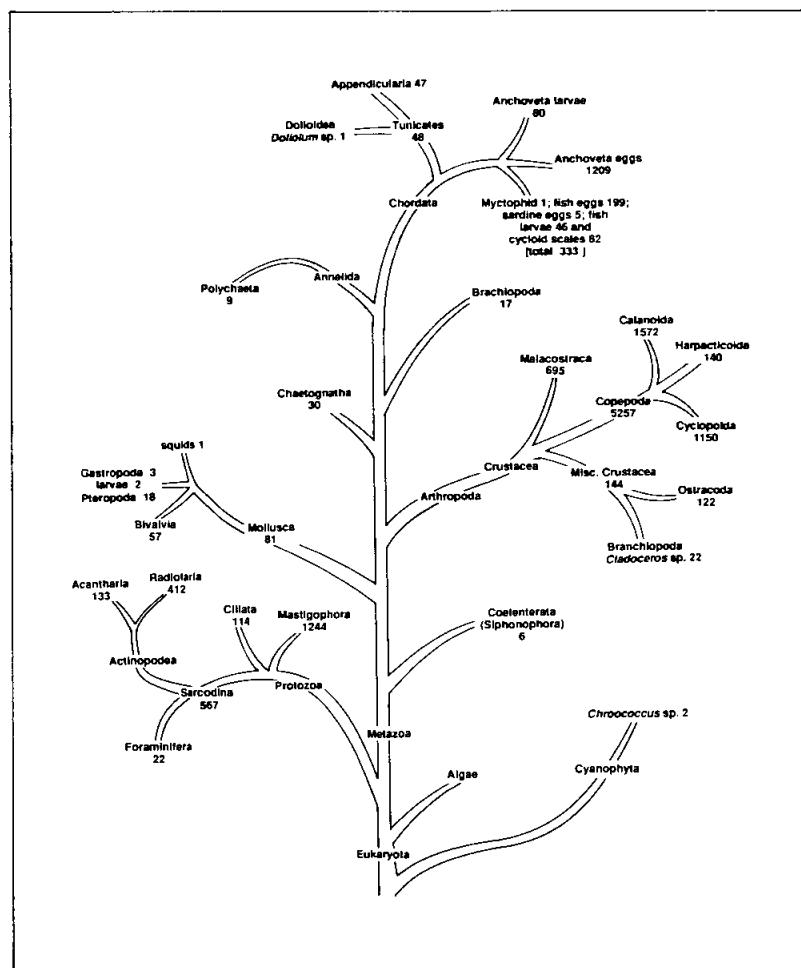

Fig. 6. Taxonomic "tree" emphasizing metazoan organisms ingested by Peruvian anchoveta, 1953 to 1982 (numbers indicate occurrences; see also Fig. 5).

Fig. 6. Diagrama taxonómico que resalta los metazoos ingeridos por la anchoveta, 1953 a 1982 (los números indican la ocurrencia, ver también Fig. 5).

Table 4 and Fig. 10 present the results of the tests of four different hypotheses relating to changes in the zooplankton fraction (ZF) in the diet of anchoveta.

These results suggest (a) that anchoveta in the northern/central part of Peru rely on zooplankton less than do their counterparts on the south of Peru, (b) that mean ZF significantly

Table 2. Taxonomic and other grouping used to describe the food of Peruvian anchoveta.
Tabla 2. Grupos taxonómicos usados para describir el alimento de la anchoveta peruana.

| Group number | Taxa included | Details in | No. of occurrences ^a |
|----------------------|----------------------------------|------------|---------------------------------|
| 1 | Miscellaneous items | Table 3 | 485 |
| <i>Phytoplankton</i> | | | |
| 2 | Fragilariaeae | Fig. 8 | 1,643 |
| 3 | Surirellineae | Fig. 8 | 1,044 |
| 4 | Misc. Pennales | Fig. 8 | 473 |
| 5 | Coscinodiscineae | Fig. 8 | 3,487 |
| 6 | Biddulphineae | Fig. 8 | 1,646 |
| 7 | Misc. Centrales | Fig. 8 | 608 |
| 8 | Mastigophora | Fig. 7 | 621 |
| <i>Zooplankton</i> | | | |
| 9 | Sarcodina + Ciliata | Fig. 7 | 1,069 |
| 10 | Misc. invertebrates ^b | Fig. 6 | 149 |

| 12 | Copepoda | Fig. 9 | 3,998 |
| 13 | Misc. crustaceans ^c | Fig. 9 | 285 |
| 14 | Misc. chordata ^d | Fig. 6 | 442 |
| 15 | Anchoveta eggs ^e | Fig. 6 | - e |

^aThese numbers do not match those in Figs. 6-9 because for those, the component taxa of all groups (1-15) were counted separately, as recorded on the raw data sheets of B. Rojas de Mendiola and of A. Alamo, while for this table, only group occurrences in the computerized database were counted.

^bIncluding Coelenterates, Chaetognaths, Polychaetes, Mollusks and Brachiopods.

^cIncluding Ostracoda and Branchiopoda.

^dIncluding tunicates, small fish, anchoveta and other fish larvae, fish scales and non-anchoveta fish eggs.

^eNot included as food item 15 in the Rojas/Alamo database; listed separately as "no. of eggs per stomach".

Table 3. Reported occurrences in anchoveta stomachs of items not attributable to any definite taxon.^a

Tabla 3. Relación de las ocurrencias en los estómagos de anchoveta de ítems no atribuibles a un definido grupo taxonómico.

| Item | Occurrences (in %) |
|-----------------------------|--------------------|
| Invertebrate eggs | 24.1 |
| Invertebrates | 1.7 |
| mucus | 3.5 |
| Unidentified material | 12.8 |
| Organic material | 0.6 |
| Plankton | 1.5 |
| Phytoplankton ^b | 29.5 |
| Zooplankton | 17.5 |
| Algae | 1.7 |
| Detritus | 5.0 |
| Fibers | 0.4 |
| Chromatophores | 1.7 |
| Total number of occurrences | 485 |

^aThese items are listed as "miscellaneous items" in Table 2.

^bIncluding 2 occurrences of Cyanophyta.

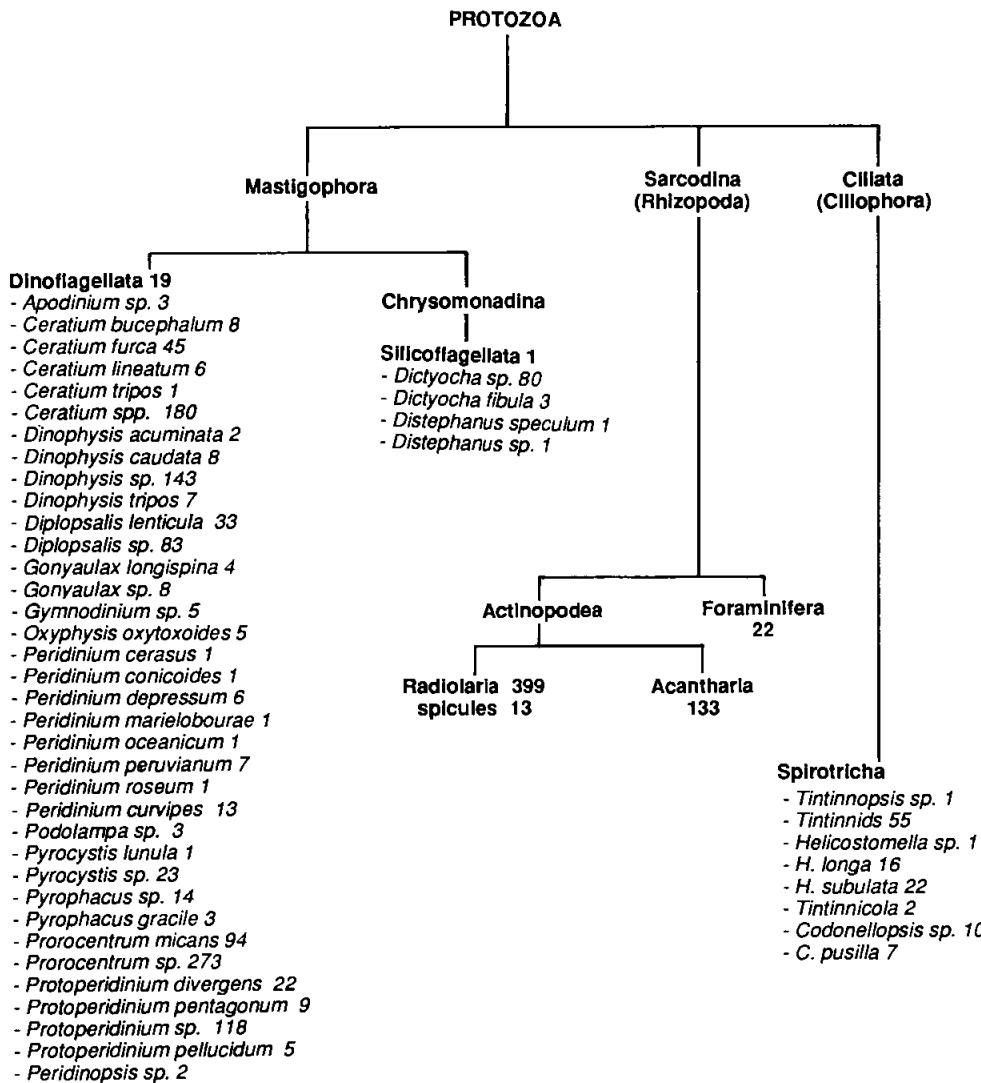

Fig. 7. Protozoan taxa ingested by Peruvian anchoveta, 1953 to 1982 (numbers indicate occurrences; see also Fig. 5).

Fig. 7. Protozoos ingeridos por la anchoveta peruana, 1953 a 1982 (los números indican la ocurrencia; ver tambien Fig. 5).

increases with offshore distance, (c) that more zooplankton is consumed when SST is high and (d) that the mean ZF values were different in the three sampling periods considered here.

Interpretation of these results is straightforward in the case of (a), (b) and (d). In the case of hypothesis (b), we have indeed a rather stunning confirmation of the process described by Vinogradov (1981) wherein a plume of upwelled water enriches itself with zooplankton as it moves "downstream" (i.e., offshore, in the case of a coastal upwelling).

Fig. 11 shows the relationship between the linearity of equation (1), expressed by means of its coefficient of determination, and different values for reexpression (in %) of "half empty" and "half full". As might be seen, 40% for half empty and 60% for half full best linearizes equation (1), given the data at hand. Fig. 12 shows the resulting plot of transformed stomach contents and fullness index.

Fig. 13 and Table 5 summarize the results of the application of Sainsbury's model I (i.e., equations 5a, 5b and 5c) to the stomach content/fullness data in the Rojas de Mendiola/Alamo database.

| <17°C | vs. ≥20°C | 7.24 | 3,644 | yes |
| 17-19.9°C | vs. ≥20°C | 8.29 | 3,676 | yes |
| Time | | | | |
| <1975 | vs. 1975-1978 | 5.99 | 4,613 | yes |
| <1975 | vs. 1979 | 3.04 | 3,842 | yes |
| 1975-1978 | vs. 1979 | 9.33 | 4,022 | yes |
| Distance from shore | | | | |
| Inshore | vs. intermediate | 4.84 | 6,158 | yes |
| Inshore | vs. offshore | 11.32 | 120 | yes |
| Intermediate | vs. offshore | 9.36 | 133 | yes |

Information on stomach contents and exact sampling time were available for 5,245 individual anchoveta (mean wet weight 20.4 g); their mean sampling year was 1977 and their mean stomach content (as obtained by direct weighting or through conversion) are plotted as a function of time in Fig. 13, and further statistics are given on Table 5.

Sainsbury's model fitted these data extremely well (mean sum of squared residuals = 0.008), and this led to the following parameter estimates (all converted from relative to absolute stomach content):

$$a = 0.0340 \text{ g} \cdot \text{hour}^{-1}, \text{ i.e., an ingestion rate of } 0.034 \text{ g} \cdot \text{hour}^{-1} \text{ during the feeding period}$$

$$T_f = 10.92 \text{ hours, i.e., anchoveta starts feeding at 10:55 a.m.}$$

$T_m = 12.81 \text{ hours, i.e., the feeding period is of } 12.81 \text{ hours and lasts until 11:45 p.m.}$
and $c = 0.1518 \text{ hours}^{-1}$, i.e., anchoveta evacuate 15.2% of their stomach content per hour.

This leads to a daily ration estimate of $R_d = 0.448 (\text{g} \cdot \text{day}^{-1})$, and hence a relative daily food consumption (% BWD) of 2.2%.

The mean growth rate, for anchoveta of 20.4 g live weight was computed based on $W_\infty = 61 \text{ g}$, $K = 1.05 \text{ year}^{-1}$ and $t_0 = 0$ (i.e., using estimates of L_∞ , K and t_0 for 1977 in Palomares et al. 1987, and based on the conversion of $L_\infty = 21 \text{ cm}$ to W_∞ using a mean condition factor of 0.661 based on the mean of the 12 monthly values given for 1977 in Tsukayama and Palomares 1987).

The resulting growth rate was $dw/dt = 0.0772 \text{ g} \cdot \text{day}^{-1}$ and hence

$$K_1 = 0.0772/0.448 = 0.2075$$

which leads, given equation (10) to $\beta = 0.173$.

These parameter estimates, led, when used in conjunction with $Z = 4.5 \text{ year}^{-1}$ (Pauly and Palomares, this vol.) and equation (11) to an estimate of $Q/B = 3.30\%$ (daily), i.e., the anchoveta population would consume 12.1 times its own weight per year (at a mean SST of 17.1°C).

These results correspond well with previous estimates obtained from metabolic studies. Palomares et al. (1987), based on Villavicencio (1981) and Villavicencio and Muck (1983a, 1983b, 1985), had estimated ration of adult anchoveta (in % BWD) to range between 3.50% ("1950" conditions) and 2.6% ("1980" conditions), thus bracketing our estimate of 3.30%/day.

Tsukayama and Sanchez (1981), based on Villavicencio (1981), and on experiments in which they fed fish flesh to anchoveta, estimated a daily consumption of 4% BWD for anchoveta of 10 g.

Cushing (1978) suggested that "the daily ration as percentage of body weight for a fish as small as the anchoveta is likely to be nearer 5% than 1%. If the mean length were 12.5 cm, a reasonable daily ration would be equal to 0.66 ml, which is 10 times the weight of algae in the guts".

Equations (6) to (11), applied to Cushing's estimate of ration for 12.5 cm anchoveta (i.e., of 13 g), and assuming 1 ml = 1 g, the same growth and mortality as used above, leads to $Q/B = 6.34\%/\text{day}$. This is markedly higher than our estimate of 3.30%, and also higher than the estimate of 2.6 to 3.5% reported in Palomares et al. (1987). However, these lower estimates are based on mixed zoo- and phytoplankton diet (mean ZF for data used to estimate $R_d = 49.6\%$, see Villavicencio and Muck (1983a, 1983b, 1985)). If one assumed, with Brett and Groves (1979), that zooplankton provides about four times more net energy than the pure phytoplankton diet considered by Cushing (1978), one can estimate as $Q/B = 3.95\%/\text{day}$ value, had he considered an equal proportion of zoo- and phytoplankton in the diet of anchoveta. This is close enough to our estimate, considering that it actually was a "guesstimate".

Our value of $E_t = 0.373$ is, on the other hand, higher than the previously estimated "growth efficiency of 0.093 ("1950") to 0.239 ("1980", see Palomares et al. 1987), and also higher than the range of 0.10-0.20 used by Chavez et al. (this vol.). However, this high value is in line with Muck (this vol.) who suggests that anchoveta has a higher growth (i.e., trophic) efficiency than sardine, for which values of up to 0.185 have been proposed (Lasker 1973).

Abstract

Monthly mean fat content data of adult Peruvian anchoveta (*Engraulis ringens*) sampled off Chimbote and Callao, Peru during 1964 to 1986 are presented. The observed seasonal and inter-year fluctuations of fat content are related to the condition factor of anchoveta and to sea surface temperatures.

Resumen

Se presentan datos mensuales del contenido de grasa en ejemplares adultos de la anchoveta peruana (*Engraulis ringens*) de las localidades de Chimbote y Callao, Perú, durante 1964-1986. Se analizan las variaciones estacionales e interanuales en relación con las variaciones de la temperatura superficial del mar y el factor de condición.

Introduction

Numerous monthly time series, covering both oceanographic and biological factors were presented in the volume edited by Pauly and Tsukayama (1987) as part of a multidisciplinary effort to identify the factors which determine the recruitment of the Peruvian anchoveta (*Engraulis ringens*).

The opportunity is taken here to add to this database a time series of monthly fat content data, representing one of the factors likely to impact on reproduction, and hence on recruitment (Pauly 1987).

The literature on bioenergetics makes abundantly clear that somatic growth, gonad maturation and reproduction occur only when the energy intake of fish exceeds their maintenance requirements (Hoar 1969; Philipps 1969; Brett 1979; Ware 1980). In adult fish, however, when maturity is attained, growth is reduced, and the bulk of the energy intake is used to build a fat reserve, which is subsequently used to form gametes. These processes are strongly influenced by environmental conditions, notably positive temperature anomalies, which increase routine metabolism. This is illustrated here by the results of studies on adult *Engraulis ringens* which show that at 15°C the maintenance ration is 2.3% body weights per day (%BWD), but increases to 5% BWD at 23°C (Tsukayama and Sánchez 1981; Villavicencio and Muck 1985).

Thus, studies of fat content dynamics, and more precisely, a model to predict the fat content of anchoveta from environmental and other data would be useful to unravel the population dynamics of anchoveta. The present contribution is an attempt to derive such predictive model.

Materials and Methods

The fat content data used for the present contribution stem from four sources:

- i) the report of Lam (1968) for the years 1968 to 1972,
- ii) from field stations ("*Laboratorios Costeros*") of IMARPE for the years 1968 to 1976,
- iii) from the archives of the state fishing enterprise PESCAPERU and from various EUREKA cruises for the years 1977 to 1986.
- iv) some of the data of Alamo (this vol.) on visceral fat stages of anchoveta for the years 1974 to 1982 were also analyzed, with emphasis on their relationship to the percentage fat content data which form the bulk of the present contribution.

The time series reconstructed from the data in (i) to (iii) has some noticeable gaps. Some of these could have been filled by pooling the data from Chimbote ($9^{\circ}05'S$) and Callao ($12^{\circ}00'S$), but this was not done, due to clear differences in the fat content of anchoveta from these two sampling sites (see below).

The fat content data presented here refer to either of three size groups:

- i) anchoveta of 12 to 14 cm TL
- ii) anchoveta ≥ 14 cm TL
- iii) "average" adult anchoveta, i.e., the mean of the values in (i) and (ii).

The available fat content data, averaged on a monthly basis were plotted against time and other variables with which they could be expected to correlate. Following a suggestion of D. Pauly (pers. comm.) a multivariate model was also derived for prediction of fat content given the condition factor (c.f.) of anchoveta (c.f. = $W \cdot 100/L^3$; TL in cm, weight in g), SST anomaly (in $^{\circ}C$) a dummy variable (loc.) expressing the sampling location (Callao = 0, Chimbote = 1), and 11 additional dummy variables expressing the month of the year (only 11 such variables are needed, i.e., when all are set at zero, the 12th month is implied).

This model had the form:

$$\% \text{ fat cont.} = a + b_1(\text{c.f.}) + b_2(\text{temp.anom.}) + b_3(\text{loc.}) + b_{4-15}(\text{month}) \quad \dots 1)$$

and was fitted using the multiple regression option of the Lotus 1-2-3 spreadsheet program.

Of the data of Alamo (this vol.) only 1,381 individual records were used (23% of the total file), pertaining to anchoveta > 12 cm LT ("adult anchoveta") and stemming from $8^{\circ}00'$ to $9^{\circ}59'S$ ("Chimbote") and $11^{\circ}00'$ to $12^{\circ}59'S$ ("Callao").

The mean monthly SST data used here for Chimbote and Callao are reproduced here as Tables 1 and 2. The c.f. data stem from Tsukayama and Palomares (1987); only actual values were used, i.e., values estimated from SST were not included in the analyses.

Results and Discussion

Tables 3 and 4 present the available monthly time series of fat content of adult anchoveta for Chimbote and Callao, respectively. A subset of these data, pertaining to the years 1964-1976 only, is presented as Figs. 1 and 2 in the form of averaged seasonal patterns. As might be seen from these figures, anchoveta caught off Chimbote have a higher fat content than those caught off Callao, particularly from April to June.

Fig. 3 depicts the seasonal trend of fat content of anchoveta expressed by the data of Alamo (this vol.). As might be seen, this trend is roughly similar to those in Figs. 1 and 2.

The basic similarity between the data in Tables 3 and 4 and those of Alamo (this vol.) is also illustrated by Fig. 4, which allowed derivation of the empirical relationship

$$\log_{10}(\% \text{ fat content}) = 1.28 + 2.21 \log_{10}(\text{c.f.}) \quad \dots 2)$$

Fig. 5 illustrates the positive relationship between the condition factor of anchoveta and its fat content. This relationship is also expressed by

$$\log_{10}(\% \text{ fat content}) = 1.28 + 2.21 \log_{10}(\text{c.f.}) \quad \dots 3)$$

which, with $r = 0.426$ and d.f. 206, is significant ($P < 0.01$).

^aNot used for Fig. 5.

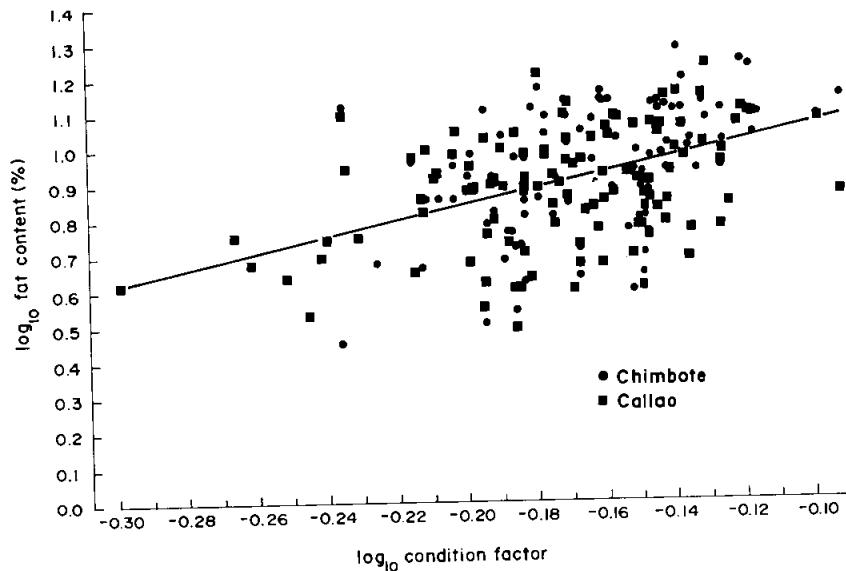

Fig. 5. Relationship between the condition factor of the Peruvian anchoveta and its fat content. Note wide scatter of data, due to inclusion of data from different months and from periods with high temperature anomalies.

Fig. 5. Relación entre el factor de condición de la anchoveta peruana y su contenido de grasa. Nótese la amplia dispersión de los datos debido a la inclusión de datos de diferentes meses y de períodos con altas anomalías de temperatura.

Table 5. Partial regression coefficients of equation (4) expressing the impact of time of the year (i.e., month) on the fat content of anchoveta (see also text and Fig. 6).

Tabla 5. Coeficientes de regresión parcial de la ecuación (4) expresando el impacto de la época del año (es decir, mes) en el contenido de grasa de la anchoveta (ver también texto y Fig. 6).

| Month | Partial regression coefficient (b_i) | s.e. of b_i values |
|-----------|--|----------------------|
| January | (0) | - |
| February | +0.987 | 0.892 |
| March | +1.110 | 0.781 |
| April | +1.346 | 0.753 |
| May | +0.689 | 0.771 |
| June | +0.712 | 0.841 |
| July | -1.660 | 1.077 |
| August | -3.155 | 1.340 |
| September | -3.830 | 0.847 |
| October | -3.360 | 0.841 |
| November | -1.670 | 0.855 |
| December | +0.774 | 0.824 |

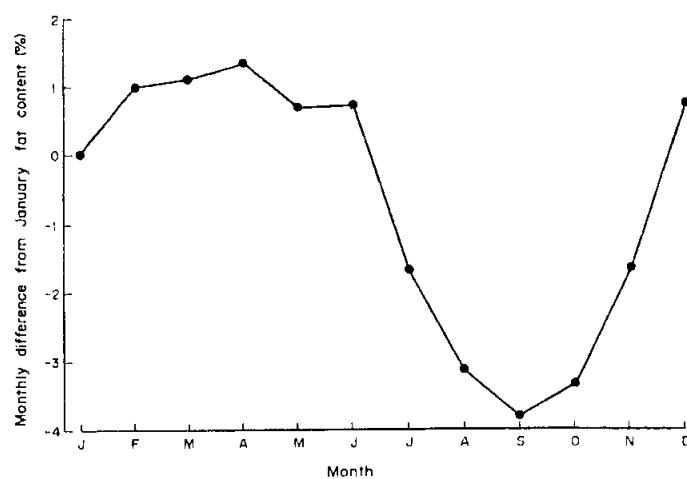

Fig. 6. Monthly change in fat content of Peruvian anchoveta, as expressed by the values of the monthly partial slopes (b_i) of equation (4). See also text and Table 5.

Fig. 6. Cambios mensuales en el contenido de grasa de la anchoveta peruana, expresada por los valores mensuales de la pendiente parcial (b_i) de la ecuación (4). Ver también texto y Tabla 5.

However, the wide scatter of this plot suggests that prediction of fat contents from condition factors alone would be very unreliable.

More useful here is the relationship

$$\% \text{fat content} = 11.2 + 28.8 (\text{c.f.}) - 0.24 (\text{temp. anom.}) + 1.02 (\text{loc.}) + b_1 (\text{month}) \quad \dots 4)$$

which has a multiple correlation coefficient $R = 0.708$ (d.f. = 187) and whose values of b_i are given in Table 5 and on Fig. 6 as well. These coefficients reproduce quite faithfully the seasonal oscillation of anchoveta fat content, and hence equation (4) can be expected to provide reasonable results when used for predictions.

PEÑA, N., J. MENDO and J. PELLÓN. 1989. Sexual maturity of Peruvian anchoveta (*Engraulis ringens*), 1961-1987, p. 132-142. In D. Pauly, P. Muck, J. Mendo and I. Tsukayama (eds.) The Peruvian upwelling ecosystem: dynamics and interactions. ICLARM Conference Proceedings 18, 438 p. Instituto del Mar del Perú (IMARPE) Callao, Perú; Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ), GmbH, Eschborn, Federal Republic of Germany; and International Center for Living Aquatic Resources Management (ICLARM), Manila, Philippines.

Abstract

Time series of gonad maturity stages of Peruvian anchoveta (*Engraulis ringens*) are presented; they cover the period 1961-1987 and the area from 6 to 18°S. An increasing trend of mean gonad stage is demonstrated which is particularly strong for the stock south of 14°S. The seasonality of gonad maturation is discussed with reference to stage, anchoveta size (age) and sampling location.

Resumen

Se presentan las series temporales del estadio de madurez gonadal de la anchoveta peruana (*Engraulis ringens*) del área 6 a 18°S para el período 1961 a 1987. El estadio de madurez promedio muestra una tendencia a incrementarse particularmente en el stock al sur de 14°S. Se discute la estacionalidad de la madurez gonadal con referencia al estadio, tamaño (edad) de la anchoveta y al lugar de muestreo.

Introduction

The Peruvian anchoveta (*Engraulis ringens*), constituted the base of the Peruvian fish meal and oil industry during the 1960s and 1970s. In view of this, the Instituto del Mar del Perú (IMARPE) and its predecessor, the Instituto de los Recursos Marinos, directed their research towards this resource, accumulating biological information on this species from the 1950s to date.

Part of this information has been analyzed and published in the book "The Peruvian Anchoveta and Its Upwelling Ecosystem: Three Decades of Change" (Pauly and Tsukayama 1987a).

The objective of the present work is to contribute to the biological data time series published in the above-mentioned book, by presenting and analyzing data on the sexual maturity of anchoveta sampled from different regions of the Peruvian coast.

*PROCOPA Contribution No. 93.

Materials and Methods

For this study, data on sexual maturity stages obtained through biological sampling of the landings of the industrial fishery have been used. The samples were grouped into three regions: north (06° - $9^{\circ}59'S$), central (10° - $13^{\circ}59'S$) and south (14° - $18^{\circ}30'S$) (Fig. 1).

Sexual maturity stages were obtained by macroscopic observation of the gonads, according to Einarsson et al. (1966) who used a 6-stage scale (see also Rojas de Mendiola, this vol.):

- Stage I Immature
- Stage II Immature or recuperating
- Stage III Maturing
- Stage IV Mature
- Stage V Spawning, and
- Stage VI Spent; postspawning

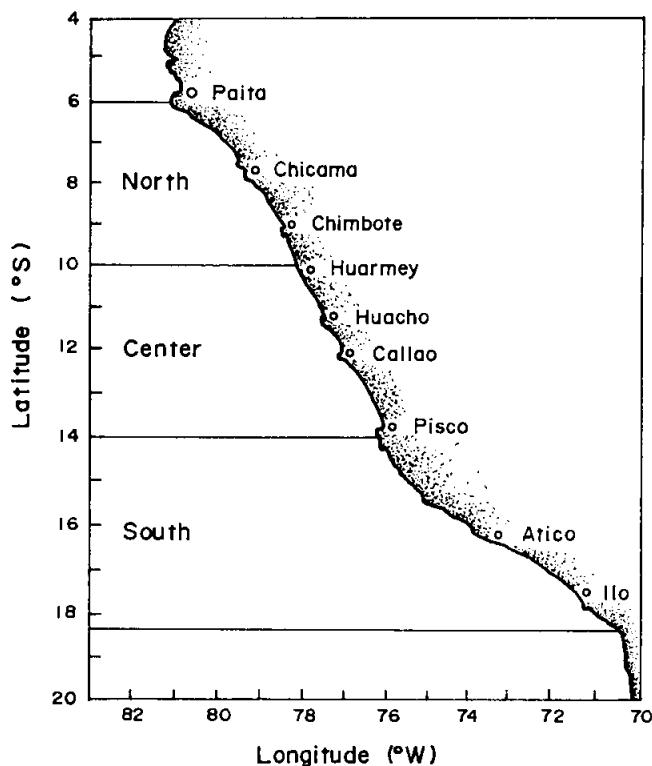

Fig. 1. Definition of northern, central and southern areas off the Peruvian coast, as used in this contribution.

Fig. 1. Delimitación de las áreas norte, centro y sur de la costa peruana usadas en ésta contribución.

Analysis and Data Processing

The frequencies (number of individuals) for each maturity stage per length and month were raised separately to the total catch of anchoveta from the northern/central region (6° - $13^{\circ}59'S$) - the main distribution area for this species - and from the southern region, where a different stock occurs (IMARPE 1973; Pauly and Tsukayama 1987b). These raised data were used to obtain the monthly mean sexual stages by length class.

Unaggregated mean monthly maturity stages by length, sex and by region are presented for the 1961-1987 period in Pellón et al. (1988), and the data presented here represent a subset of those compiled in that paper. Particularly, we do not report here our results on a length-class basis.

Results and Discussion

Variation of the Mean Maturity Stages

Table 1 and Figs. 2 and 3 show the monthly mean values of sexual maturity in the northern/central and southern stocks of adult anchoveta (≥ 10.25 cm), for the 1961-1987 period. As might be seen, these values tend to increase through time, especially so in the south.

The highest mean maturity stages generally occurred, for both stocks, during the spring and summer months, when stages IV, V and VI predominate (see Table 1).

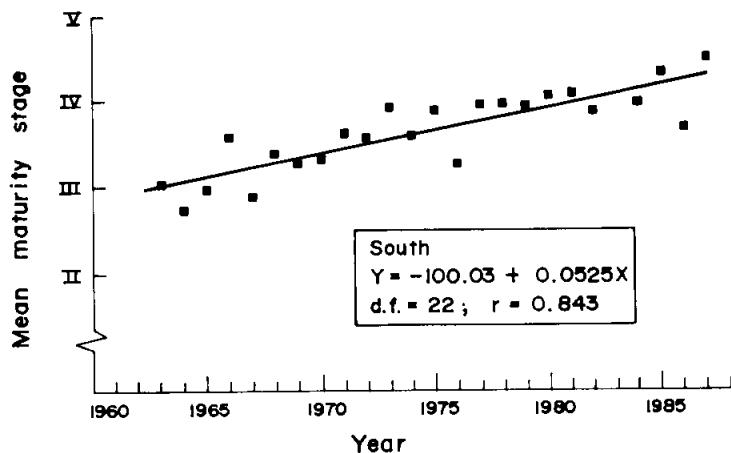

Fig. 2. Trend of mean annual maturity stage of anchoveta, 1961-1987 off northern/central Peru (based on data in Table 1 with missing months replaced by the appropriate monthly means before averaging).

Fig. 2. Tendencia del estadio de madurez promedio anual de la anchoveta del área norte/central del Perú para 1961-1987 (basado en datos de la tabla 1; para los meses sin datos se usaron el promedio mensual antes de promediar el valor anual).

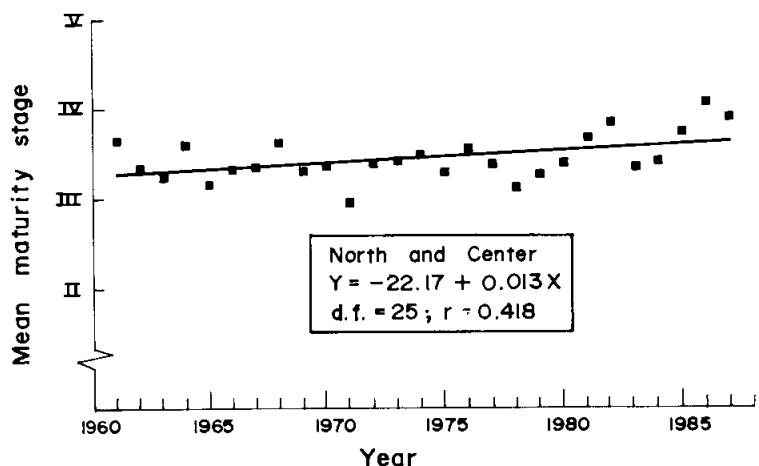

Fig. 3. Trend of mean annual maturity stage of anchoveta, 1963-1987 off southern Peru (based on data in Table 1 with missing months replaced by the appropriate monthly means before averaging).

Fig. 3. Tendencia del estadio de madurez promedio anual de la anchoveta del área sur del Perú para 1963-1987 (basado en datos de la Tabla 1; para los meses sin datos se usaron el promedio mensual antes de promediar el valor anual).

Variation of the Maturity Stages

Both the northern/central and the southern stocks show a large fraction of individuals to be in stage I during the 1960s and 1970s. Additionally, low values were observed in the northern/central stock in 1961-1963 and from 1971 to 1987, except for 1976, and in the southern stock in 1968-1969 and from 1971 to 1987, except for 1981 (Table 2).

Table 3 gives the percent values of stages II + III. These oscillated markedly during 1963-1966, especially in the southern stock. The lowest values in this stock are obtained during 1963-1966 and 1979-1984, and the highest in 1967-1977 and from 1986 on; for the northern/central stock, the lowest values belong to the 1971-1976 period, which was followed by relatively high values from 1968 on. Both stocks generally have their highest values in the winter months.

Table 1. Mean monthly sexual maturity stage of adult female and male anchoveta (≥ 10.25 cm TL) in the northern/central and southern areas of Peru, 1961-1987.

Tabla 1. Valores mensuales promedios del estadio de madurez sexual para anchoveta, hembras y machos adultos (≥ 10.25 cm LT) del stock del norte/centro y sur del Perú, 1961-1987.

Stage IV (Table 4) shows no large fluctuations in the northern/central stock, except for 1978 and 1987. The highest values are generally observed in spring and summer, and the lowest during the autumn and early winter months. The southern stock shows greater fluctuations than the northern/central stock, with low values during 1963-1974. From 1975 on, an increase can be observed, and a maximum is reached in spring 1982.

In both stocks, the highest values occur in spring and the lowest in autumn-winter.

The mean values of stages V and VI (Table 5) in the northern/central stock were relatively constant during 1961-1971, while high values occurred in 1962, 1965, 1968-1969 and 1985-1987. The maximum values occur in the spring months and the minimum in autumn.

The southern stock does not present marked tendencies and the mean values show similar variations through time.

The highest values tend to occur in the spring months, and the lowest in autumn and early winter.

Annual Cycles of Maturity Stages

Fig. 4 shows the seasonal cycles of maturity stages I to VI for the 1960s and 1970s for the northern/central stock, while Fig. 5 shows the corresponding data for the southern stock.

As might be seen, the monthly variations and the annual cycles of the different maturity stages confirm the results obtained by other authors on maturation and spawning of the Peruvian anchoveta (Miñano 1958, 1968; Jordán and Chirinos de Vildoso 1965; Einarsson et al. 1966; Santander and Sandoval de Castillo 1969; Jordán 1980; Santander 1981; Peña and Carrasco, MS).

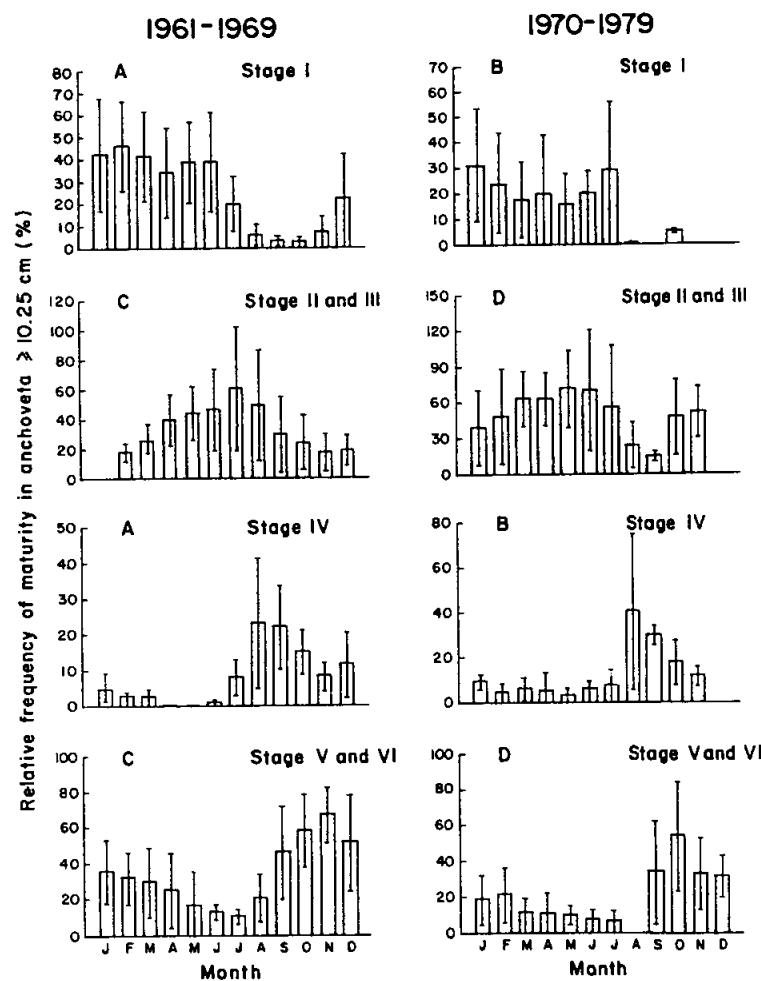

Fig. 4. Relative frequency of maturity stages I-VI in anchoveta sampled off northern/central Peru, from 1961 to 1969 and 1970 to 1979.

Fig. 4. Frecuencia relativa de los estadios de madurez I-VI de anchovetas muestreadas en el área norte/central del Perú durante 1961 a 1969 y de 1970 a 1979.

Table 4. Relative frequency (%) of sexual maturity stage IV of male and female anchoveta (6.25 - 19.25 cm TL) in the northern/central and southern areas of Peru, 1961-1987.

Tabla 4. Frecuencia relativa (%) del estadio de madurez sexual IV para anchoveta machos y hembras (6.25 - 19.25 cm LT) en las áreas norte/centro y sur del Perú, 1961-1987.

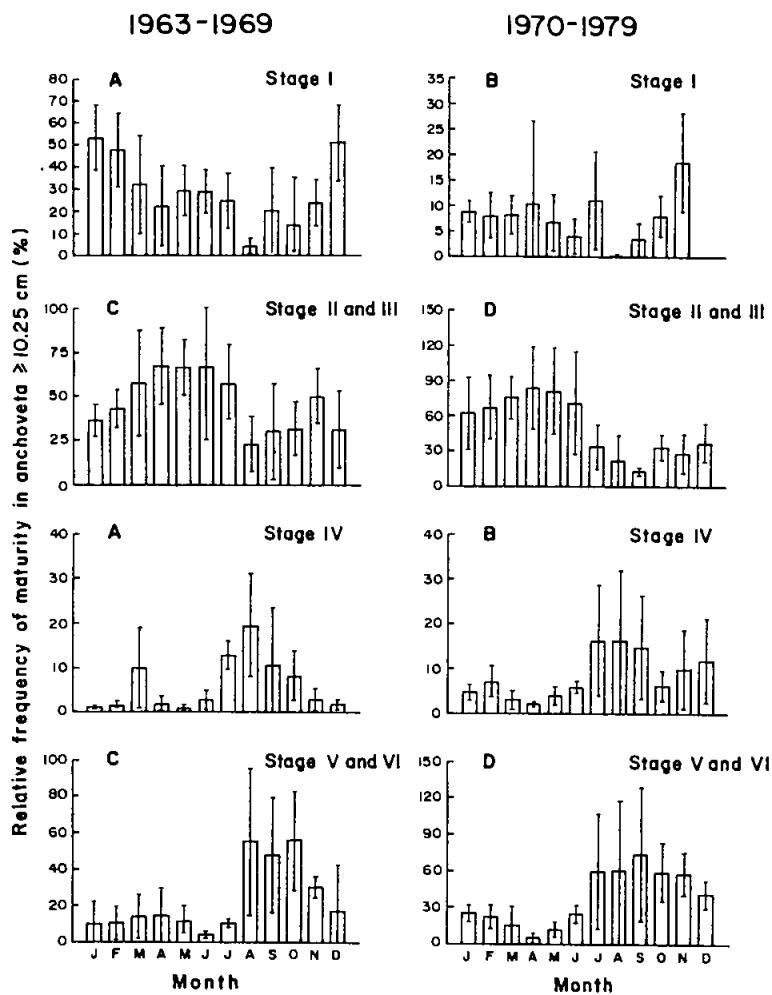

Fig. 5. Relative frequency of maturity stages I-VI in anchoveta sampled off southern Peru from 1963 to 1969 and 1970 to 1979.

Fig. 5. Frecuencia relativa de los estadios de madurez I-VI de anchovetas muestreadas en el área sur del Perú durante 1963 a 1969 y de 1970 a 1979.

Consistent differences between the northern/central and the southern stock did not appear. Maturity stage I showed its highest percentages during the 1960s, a period in which a large quantity of juvenile fish were caught (IMARPE 1965).

Acknowledgements

We want to thank Messrs. Manuel Flores, Mario Ramirez, Daniel Rojas and Juan Rubio for various assistance in preparing this contribution. Our thanks also go to Mr. Carlos Aranda for his help in the translation of the Spanish draft.

Abstract

This contribution is based on the detailed analysis (resolution: half-degree squares) of 90 maps of anchoveta (*Engraulis ringens*) egg standing stock off Peru (4-14°S), published in 1987 by H. Santander (IMARPE, Callao, Peru). It pertains to surveys conducted from 1964 to 1986. Monthly means were computed for each half-degree square using 3x3x3 running averages, i.e., involving all adjacent squares of a given month and square, and the adjacent squares of the preceding and following months. Monthly maps of egg distribution are presented, averaged over the periods 1964 to 1971 and 1972 to 1986, which are the phases preceding and following the 1972-1973 El Niño and the coincident stock collapse, respectively.

It is shown that the center of gravity of anchoveta egg production has shifted to the south along the coast. Also, the relationship between the two egg production seasons (August-October, January-March) has changed: egg production was much higher in spring than summer from 1964 to 1971, but was, from 1972 to 1986, slightly higher in summer. Overall, mean daily egg production was reduced from about 3.13×10^{13} in 1964-1971 to about 2.2×10^{13} in 1972-1986.

Resumen

Esta contribución se basa en un análisis detallado (resolución: cuadrado de medio grado) de 90 mapas de producción de huevos de anchoveta (*Engraulis ringens*) frente a Perú (4-14°S), publicados en 1987 por H. Santander (IMARPE, Callao, Perú). Estos se refieren a prospecciones realizadas de 1964 a 1986. Los promedios mensuales fueron calculados para cada cuadrado de medio grado usando promedios móviles de 3x3x3; esto es, involucrando todos los cuadrados adyacentes de un determinado cuadrado y mes, y los cuadrados adyacentes del mes precedente y siguiente. Se presentan mapas mensuales de distribución de huevos, promediados para los períodos 1964 a 1971 y 1972 a 1986, que son las fases precedente y siguiente al Niño 1972-1973 y el coincidente colapso del stock, respectivamente.

Se muestra que el centro de gravedad de la producción de huevos de anchoveta se ha desplazado al sur. Asimismo, la relación entre las dos estaciones de producción de huevos (Agosto-Octubre, Enero-Marzo) ha cambiado: la producción de huevos fué mucho mas alta en primavera que en el verano de 1964 a 1971, pero fue ligeramente mas alta en el verano de 1972 a 1986. En general, el promedio diario de producción de huevos se redujo de alrededor de 3.13×10^{13} en 1964-1971 hasta alrededor de 2.2×10^{13} en 1972-1986.

*ICLARM Contribution No. 503.

Introduction

The anchoveta (*Engraulis ringens*) once supported off Peru the largest single-species fishery of the world (Tsukayama and Palomares 1987). The collapse of this fishery, coincident with the 1972-1973 El Niño, has been, in earlier years, attributed to this hydrographic anomaly but the data presently available suggest that the purse seine fishery was the main culprit (see Muck, this vol.). The need to better manage this resource makes it particularly important to identify the key factors which determine recruitment of anchoveta. The present study is concerned with a process most likely to belong to these factors: the apparent rate of production of eggs by the anchoveta stock. The word "apparent", which will be omitted henceforth, refers to the fact that the rates of egg production derived and presented further below do not account for egg mortality, which is covered by Pauly and Soriano (this vol.).

Also, the geographical distribution of this egg production will be presented. However, due to limitations of the available data, the pertinent maps will refer only to monthly 'climatological' averages for two periods - 1964 to 1971 and 1972 to 1986. This division of the available data into two sets was chosen to cover two crucial phases: one of high anchoveta biomasses, lasting from the beginning of egg survey work to the 1972-1973 El Niño, and of generally low, but highly variable biomasses, lasting from 1972 to 1986 (see Pauly and Palomares, this vol.).

Materials and Method

The present contribution, extracted from Senocak (1988), is based entirely on the 90 maps of egg distribution in Santander (1987), pertaining to the area off Peru comprised between 4 and 14°S and based on surveys conducted from 1964 to 1986. Santander (1987) provides details on these surveys. Of this information, only the map number, the year and the month are reported here (Table 1). Sampling was performed from 50 m to the surface with a Hensen net 175 cm long, 70 cm aperture diameter and 300 mm meshes.

Table 1. Within- and between-year availability of anchoveta egg distribution maps used for this contribution.^a

^a Numbers for different months and years refer to the map numbers in Santander (1987).

The original station records were not accessible to the authors; hence, this work is based on the maps of egg abundance assembled since 1964 by H. Santander and colleagues at IMARPE, of which all had been redrawn at ICLARM, Manila, using a base map and standardized labeling schemes (Table 2).

The surveys documented through Santander's maps did not all cover the investigation area as defined in Fig. 1. However, no large-scale interpolation or extrapolation were undertaken here to compensate for this deficit. Rather, strict rules were applied for small-scale (within half-degree square) interpolations (Fig. 2), i.e., larger areas not covered during a given survey were not included in any of the analyses.

Each half-degree square included in the analysis was divided up into 100 subunits and the egg abundance (d) estimated for each subunit, based in class means in Table 2.

Table 2. Class limits and assumed class means of anchoveta egg abundance maps in Santander (1987), in eggs/m².

Tabla 2. Límites de clase y clase media asumida de los mapas de densidad de huevos de anchoveta presentados por Santander (1987), en huevos/m².

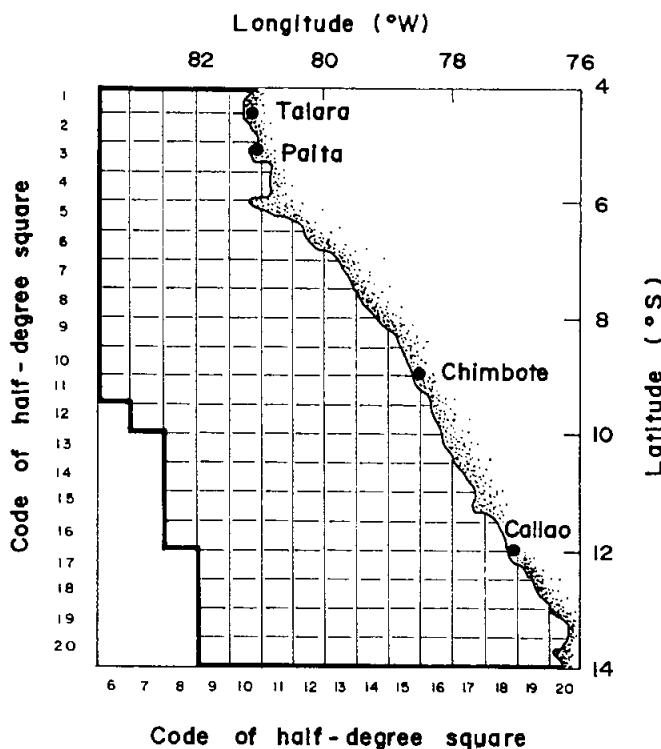

Fig. 1. Investigation area off Peru (4-14°S) showing towns mentioned in the text and numbering system for the 182 half-degree squares used to digitize information in the 90 egg distribution maps of Santander (1987). Area includes only half-degree squares covered during at least one egg survey from 1964 to 1986.

Fig. 1. Área de investigación frente a Perú (4-14°S), mostrando los lugares mencionados en el texto y el sistema de numeración para los 182 cuadrados de medio grado, usados para registrar la información de los 90 mapas de distribución de huevos reportados por Santander (1987). El área incluye sólo a los cuadrados de medio grado donde se realizó por lo menos una prospección de huevos de 1964 a 1986.

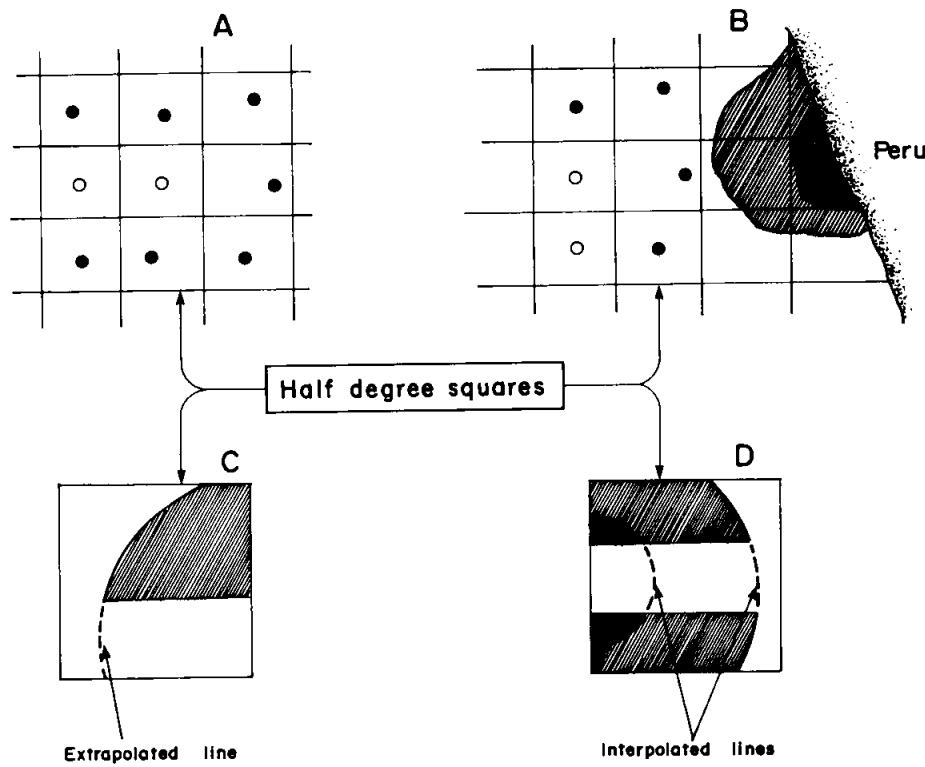

Fig. 2. Schematic representations of rules for interpretation of maps in Santander (1987). A: In cases where half-degree squares without observation (○) were surrounded by zero observation (●), the encircled squares were assumed to also contain a zero observation. B: When isolines of egg densities along the coast were clearly delimited by zero values, seaward squares without observations were assumed to contain no eggs. C and D: Interrupted isolines in maps, due to missing stations, were extrapolated or interpolated by eye, following the trend of the lines within the half-degree squares.

Fig. 2. Representación esquemática de reglas para la interpretación de los mapas de Santander (1987). A: En los casos donde el cuadrado de medio grado sin observación (○) esta indicado por observación cero (●), se asume que el cuadrado circundante también contiene observación cero. B: Cuando las isolíneas de densidades de huevos a lo largo de la costa están claramente delimitadas por valores cero, se ha asumido que los cuadrados hacia la costa y sin observaciones tampoco contiene huevos. C y D: Las isolíneas interrumpidas en los mapas, debido a estaciones ausentes, fueron extrapoladas o interpoladas al ojo, siguiendo la tendencia de las líneas dentro del cuadrado de medio grado.

The mean abundance of eggs per m² (E_j) in a given half degree during a given survey and square (j) was then estimated from:

$$E_j = (\sum n_1 d_1) N_j^{-1} \quad \dots 1)$$

where N_j is the number of subunits in square (j), n₁ the number of subunits of a given egg abundance level (see Table 2), and d₁ the mean number of eggs per m² for that group of subunits. Note that directly under the coast, squares with N < 100 were rather frequent (see Fig. 1).

The estimated development time of anchoveta eggs were taken, for the years 1964-1982 from Table 3 in Santander (1987). For the following period, which lasted to the end of 1986, development time (D, in days) was estimated from

$$\log_{10} D = 6.953 - 4.09 \log_{10} (T + 26) \quad \dots 2)$$

where T is the sea surface temperature (SST, in °C), and which was derived by Pauly (1987) from equation (5) in Pauly and Pullin (1988) and from empirical data in Santander and Sandoval de Castillo (1973). The temperature used to represent the Peruvian coast from 4 to 14°C south for the years 1982-1986 are means of the monthly temperatures for Talara, Paita, Chimbote and Callao (see Table 2 and Figs. 3 and 4).

Daily anchoveta egg production per m² (Pd) was then computed, for each half-degree square (j) and each survey/month using

$$P_{dj} = E_j * D_{-1} \quad \dots 3)$$

The resulting maps turned out to have numerous gaps and were rather difficult to interpret. Therefore, a 3x3x3 interpolation scheme (see Fig. 5) was used to smoothen the data. This resulted in the elimination of gaps while simultaneously leading to the emergence of interpretable spatial patterns. Without missing values, the smoothing scheme in Fig. 5 will not lead to biased means, but to reduced variance (Sager 1971).

After smoothing, the monthly values of Pdj were averaged for the periods 1964 to 1971 and 1972 to 1986.

Santander's maps were Mercator projections, i.e., the east-west extent (e.g., in km) of a one-degree "square" changes with latitude (see Table 4). These values were used to convert the smoothed egg production estimates per m² within each half-degree square into production estimates per total area.

Finally, the geographic center of gravity of the anchoveta egg production was computed for each of the 12 months in the two periods by multiplying the production in each half-degree square by the latitude and longitude of its center, then computing the (weighted) average latitudes and longitudes by month.

Results and Discussion

The smoothed "climatological" maps of monthly anchoveta egg production obtained here for the periods 1964 to 1971 and 1972 to 1986 are presented here in Figs. 6a, 6b, 6c and 6d. As might be seen, maximum egg production generally occurs in a single band right along the coast, although there are indications in certain months (e.g., February or October, first and second period) of two distinct spawning "centra" (*sensu* Mathisen, this vol.), one at about 8°S, the other at about 13°S.

The center of gravity for both series (1964 to 1986) and all months combined is 9°42'S, which is very close to the value of 9°48'S that can be estimated from Table 2 of Santander (1987). This implies that Santander's large-scale extrapolation of limited surveys (and maps) to

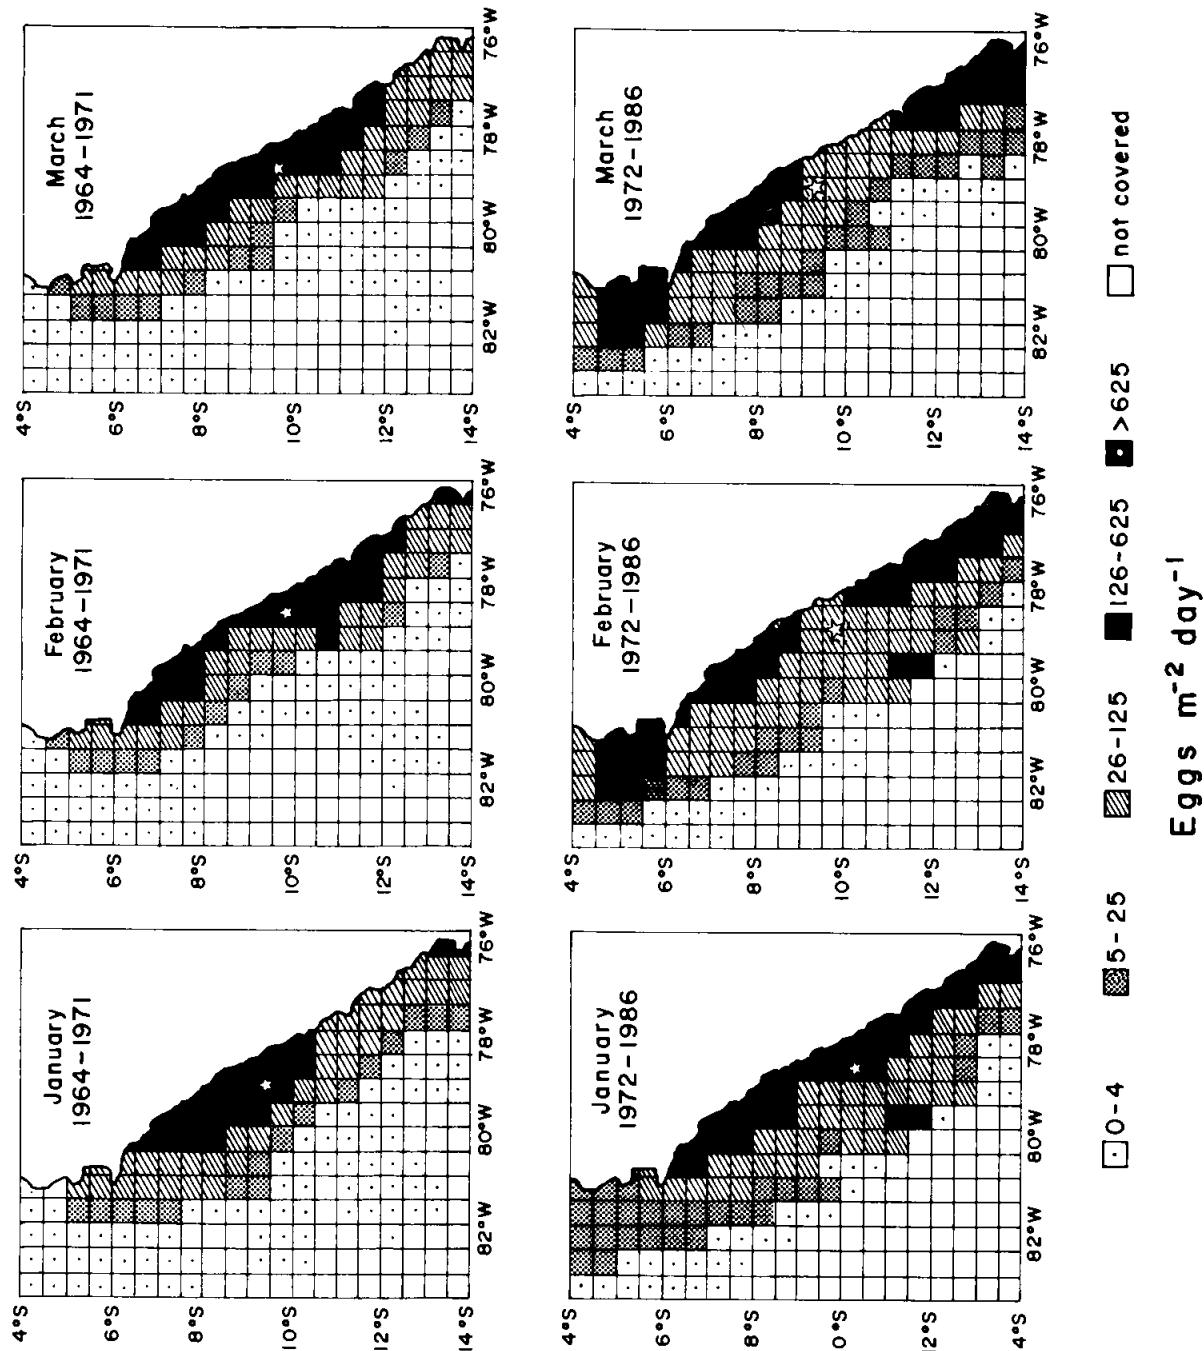

Fig. 6a. Geographic distribution of mean monthly anchoveta egg production ($\text{eggs}/\text{m}^2/\text{day}$) for the months of January, February and March during two periods (above 1964-1971; below 1972-1986). The large white star indicates center of gravity of the production values.

the whole of the northern-central coast of Peru ($4\text{-}14^{\circ}\text{S}$) did not lead to any bias that would shift the north-south balance.

Fig. 7 presents the center of gravity of anchoveta egg production off Peru on a monthly basis, for each of the two periods distinguished here. As might be seen, spawning of anchoveta in 1972-1986 involved more seasonal changes than it did in 1964-1971.

Also, a shift southward along the coast appears to have occurred. This may be in line with the "southernization" hypothesis of Palomares et al. (1987), which states that *Engraulis ringens* off northern/central Peru have become, over the last decades, more similar to their southern counterparts - in terms of various aspects of their biology - than they were earlier.

Fig. 8 presents, finally, monthly averaged estimates of total anchoveta egg production off Peru ($4\text{-}14^{\circ}\text{S}$) for the two periods considered here. The similarity between the two curves involves:

- i) evidence of two peaks per year, one lasting from January to March ("summer"), the other from August to October ("spring") and

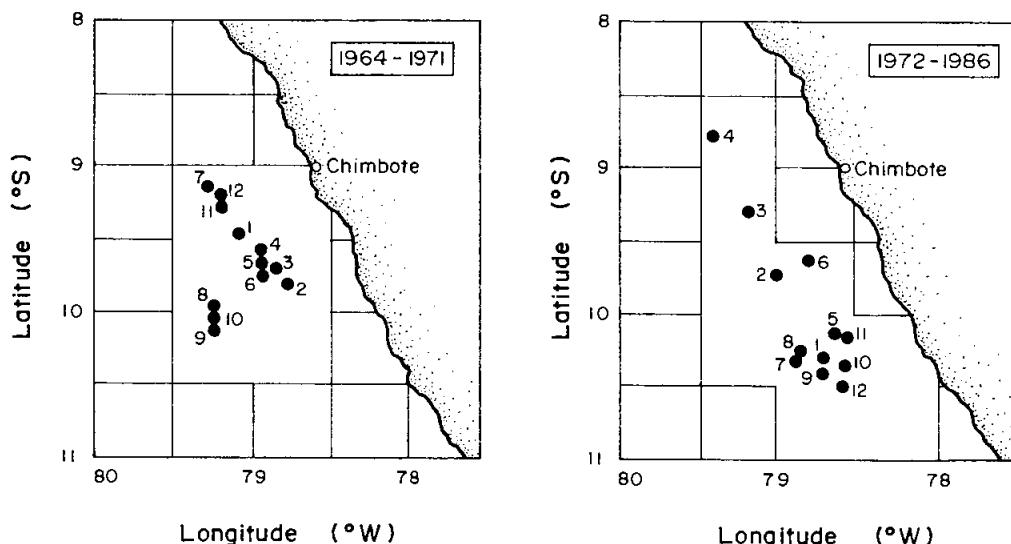

Fig. 7. Location changes of center of gravity of anchoveta egg production along the Peruvian coast, $4\text{-}14^{\circ}\text{S}$ (1-12 = January-December). Left: monthly changes from 1964 to 1971. Right: monthly changes from 1972 to 1986. (Note wider range and southeastern shift in later period.)

Fig. 7. Cambios en la ubicación de los centros de gravedad de producción de huevos de anchoveta a lo largo de la costa peruana, $4\text{-}14^{\circ}\text{S}$ (1-12 = Enero-Diciembre). Izquierda: Cambios mensuales de 1964 a 1971. Derecha: Cambios mensuales de 1972 a 1986. (Nótese para los últimos años una mayor amplitud y un cambio hacia el sur).

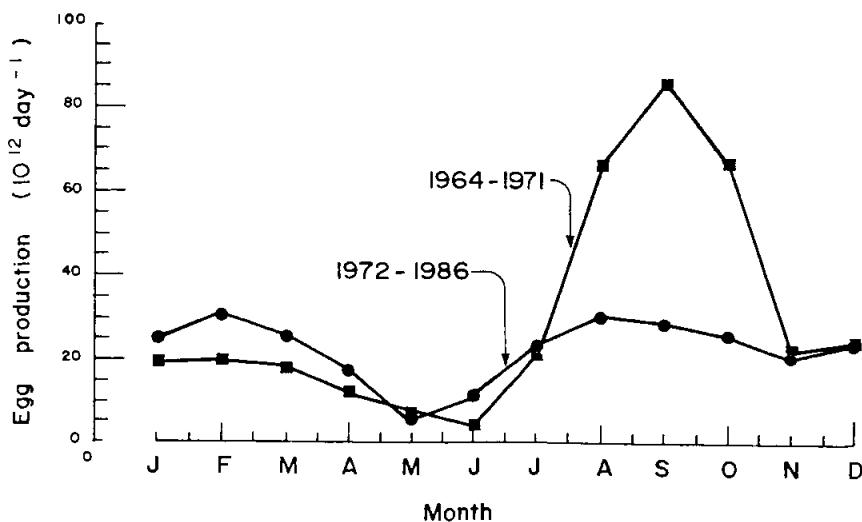

Fig. 8. Mean monthly egg production of anchoveta off Peru ($4\text{-}14^{\circ}\text{S}$) for the periods before and after the 1972/1973 El Niño. (Note marked difference in the September peak.)

Fig. 8. Promedios mensuales de producción de huevos de anchoveta frente a Perú ($4\text{-}14^{\circ}\text{S}$) para los períodos anterior y posterior al Niño 1972/1973. (Nótese la marcada diferencia en el máximo de Septiembre).

ii) a production minimum in May-June ("fall").

However, it is the difference between these two curves which strikes us most. In the first period (1964-1971), the spring peak was much larger than the summer peak, while both peaks are more or less equal in the second period (1972-1986).

A number of hypotheses could be presented to explain this large difference (Senocak 1988). However, as pointed out in the Introduction, the egg production rates estimated here are *apparent* rates, i.e., they do not account for egg mortality. We shall, therefore, abstain from suggesting here a cause for the change reflected in Fig. 8. The reader is invited, however, to consult Pauly and Soriano (this vol.) for a follow-up on anchoveta egg production and mortality.

Acknowledgments

We thank Mr. Rainer Froese, Abteilung Fischereibiologie, Institut für Meereskunde, Kiel, for his assistance with the programs needed for the digitization of Ms. H. Santander's maps, and Mr. Jaime Mendo, Instituto del Mar del Perú, Callao, for the sea surface temperature data presented here as Table 3.

Abstract

The egg production of anchoveta was estimated by month from 1953 to 1985 based on estimates of mature female biomass batch fecundity and related factors for the period 1953-1985 off Peru (4-14°S). These theoretical estimates of production were related to empirical estimates derived from egg surveys conducted from 1964 to 1985. This yielded estimates of egg mortality; a multiple regression model including parent stock size, sardine biomass, SST and SST anomaly explained a large fraction of the variance of these egg mortality estimates. However, how results suggest parent concentration (rather than parent stock size) to be the key parameter affecting anchoveta egg mortality, a hypotheses which will have to be tested in a future contribution.

Resumen

Se estimó la producción de huevos mensual de la anchoveta peruana (4-14°S) de 1953 a 1985 basado en estimaciones de la fecundidad biomasa de hembras maduras y factores relacionados para el período 1953-1985 frente a Perú (4-14°S). Estas estimaciones de producción teóricas fueron relacionadas con estimaciones empíricas obtenidas de cruceros de evaluación de huevos realizados de 1964 a 1985. Esto proporcionó estimaciones de mortalidad de huevos; un modelo de regresión múltiple que incluye el tamaño del stock de padres, biomasa de sardina, TSM y anomalías de TSM, explicó una gran parte de la varianza de estos estimados de mortalidad de huevos. Sin embargo, como los resultados lo sugieren, la concentración de padres (más que el tamaño del stock de padres) es el parámetro clave que afecta la mortalidad de huevos, una hipótesis que deberá ser probada en una contribución futura.

Introduction

Recruitment to a stock depends on (i) the size of the spawning stock and (ii) the survival of the eggs and larvae. Within fishery biology, an immense literature exists on how to forecast the recruitment of fish stock given a knowledge of spawning stock size, i.e., from the "top-down" (reviews in Ricker 1954; Cushing 1988). There have also been numerous attempts to approach the recruitment problem from the "bottom-up", i.e., through detailed analyses of the factors controlling the survival of eggs and larvae (see, e.g., papers in Sharp 1980 and Rothschild 1986).

While generally, "bottom-up" approaches have been more costly, more data intensive, yet less successful than "top-down" approaches in providing management advice, it is nevertheless clear that management of important fish resource species should be based on an understanding of all aspects of their life history, including the early stages.

In the case of the Peruvian anchoveta, sufficient data are available on the dynamics of the parent stock, and on the distribution and density of the eggs to justify an attempt to identify the major causes of anchoveta egg mortality.

*ICLARM Contribution No. 507.

Materials and Methods

Two sources of data were tapped for this contribution:

- i) length-structured biomass estimates obtained by VPA (Pauly and Palomares, this vol.) and which were used to estimate parent biomass, mature female biomass and egg production, by month, for the period January 1953 to July 1985, using a model to be briefly described further below; and
- ii) Ninety maps of anchoveta egg distribution based on egg surveys conducted from 1964 to 1985, and which were published and subjected to preliminary analyses by Santander (1987) and Senocak et al. (this vol.).

The model used here to estimate the monthly reproductive output (RO), i.e., egg production, of anchoveta has the form:

$$RO_i = \sum_{j=1}^n B_{ij} \cdot P_{ij} \cdot A_j \cdot S_k \cdot PF_j \cdot RF \quad \dots 1)$$

where j is the number of length classes for which, in a given month i , anchoveta biomass estimates are available (see Table 1 for the definition of the other terms).

Fig. 1 gives an example of the type of maps published by Santander (1987) and the first five columns of Table 2 summarize the key information pertaining to or extracted from these maps. Most important here is the fifth column, i.e., the estimates of egg standing stock, derived by planimetry (Santander 1987). [Some of these maps represented surveys which had covered less than the 4-14°S stretch of the Peruvian coast used here as reference. The estimated egg standing stocks for these maps have been, in these cases, extrapolated to the whole reference area using a procedure documented in Santander (1987). The detailed planimetry of Senocak et al. (this vol.), which did not involve any large-scale extrapolation, shows that no detectable bias was introduced by Santander's extrapolation procedure.]

Table 1. Specifications of the multiplicative model used by Pauly and Soriano (1987) to estimate the egg production of Peruvian anchoveta (equation 1), by month (i), based on biomass data by length class (j).^a

Tabla 1. Especificaciones del modelo multiplicativo usado por Pauly y Soriano (1987) para estimar la producción de huevos de anchoveta (ecuación 1) por meses (i) basado en datos de biomasa por clase de longitud (j).^a

| Variable or constant | Definition | (units) | Remarks and/or source of estimate |
|----------------------|---|-----------------|---|
| B_{ij} | Biomass of male and female anchoveta | (tonnes) | From VPA III output of Pauly and Palomares (this vol.) |
| P_{ij} | Fraction of mature fish | (dimensionless) | Derived from logistic curve with shape and position varying with SST (see Pauly and Soriano 1987) |
| A_j | Size-specific factor relating anchoveta fecundity per unit weight to length | (dimensionless) | See Tables 2 and 3 in Pauly and Soriano (1987) |
| S_k | No. of spawnings per month, $k=1$ (January); $k=12$ (December) | (1/t) | From Table 3 in Pauly and Soriano (1987), based on Jordan (1980) |
| PF_j | Fraction of females in parent stock | (dimensionless) | From Fig. 4 and Table 3 in Pauly and Soriano (1987), based on Clark (1954), Miñano (1958) and Jordan (1959) |
| RF | Relative batch fecundity | (eggs/g) | Value of 596/g female taken from Santander et al. (1984) |
| 10^9 | Factor for adjusting gram to tonne | (dimensionless) | Used, but not given in Equation (1) |
| n | Number of length classes used in month (i) | (dimensionless) | Variable between months |

^a See Pauly and Soriano (1987) for further details on model derivation and specification and on data sources.

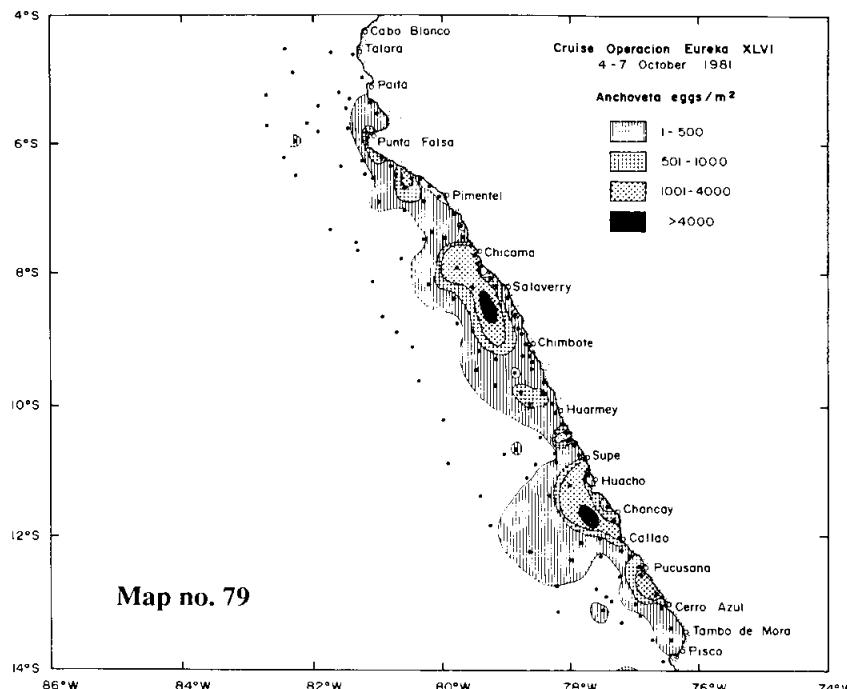

Fig. 1. Anchoveta egg distribution off Peru (4-14°S), in early October 1981. Details on this map (No. 79 in Santander 1987), given here as an example, are provided in Table 2.

Fig. 1. Distribución de huevos de anchoveta frente al Perú (4-14°S) a comienzos de Octubre 1981. Detalles de este mapa (No. 79 en Santander 1987), presentado aquí como un ejemplo, se dan en la Tabla 2.

Pauly (1987) had attempted to estimate anchoveta egg mortality by relating theoretical egg production (as estimated via equation 1), to the egg standing stock in Santander's maps. However, the model he used to calculate egg mortality (his equation 4) produced biased estimates when egg mortality was low (J.A. Gulland, pers. comm. to D. Pauly, December 1987), and his whole section on "the cannibalization of anchoveta eggs" (inclusive of his Table 2 and Fig. 4) is thus erroneous.

We used instead an approach suggested by J.A. Gulland (pers. comm.). Defining N_d as the egg standing stock at the end of period D, and R as the initial size of a "cohort" of anchoveta eggs, it follows for that cohort, that:

$$N_d = R e^{-ZD} \quad \dots 2)$$

where Z is the egg mortality from spawning/fertilization to hatching and D (days) is the egg development time. The parameter D can be estimated from:

$$\log_{10} D = 6.953 - 4.09 \log_{10}(T+26) \quad \dots 3)$$

where T is the sea surface temperature (SST, in °C) and which was derived by Pauly (1987) based on data in Santander and Sandoval de Castillo (1973) and equation (5) in Pauly and Pullin (1988).

Under steady-state condition (assumed here to prevail shortly before, during and after a given egg survey was conducted and/or during a period of one month), equation (2) implies a mean standing stock (\bar{N}) whose value can be estimated from:

$$\bar{N} = \frac{1}{D} \int_0^D R e^{-ZD} \quad \dots 4)$$

or

$$\bar{N} = \frac{R}{ZD} (1 - e^{-ZD}) \quad \dots 5)$$

^a Adapted from Santander (1987, Table 3).

^b From (part of) equation (1) and biomasses estimated by Pauly and Palomares (this vol.).

^c From Table 1 in Muck (this vol.), with monthly values interpolated between annual means (used from June/July); these estimates are very crude and need refinement, based on future VPA estimates of sardine biomasses.

^d From equation (3) and SST in Pauly and Tsukiyama (1987) for 1953 to 1982, and from Senoak et al. (this vol.) from 1983 to 1985.

^e From equation (6).

^f From equation (9).

^g Outlier, not used for estimates of parameters of equations (6) and (9).

Both N and R can be turned into egg production rates through division by D, i.e.,

$$\frac{N/D}{R/D} = \frac{1 - e^{-ZD}}{ZD} \quad \dots 6)$$

N/D then corresponds to the above-mentioned map standing stock estimates divided by egg development time (see also Senocak, this vol.), while R/D corresponds to the output of equation (1), reexpressed on a daily basis.

Various plausible multiple regression models were then applied to the data of Table 2, our aim being to identify biologically acceptable factors explaining the observed variability in egg survival. The Rojas/Alamo database on anchoveta food and feeding habits (see Rojas de Mendiola, this vol.; Alamo, this vol.; and Pauly et al., this vol.) was also tapped for data on anchoveta egg cannibalism and the results were used to help interpret the output of our egg mortality models.

Results and Discussion

Parental Biomass and Egg Production, 1953 to 1985

Fig. 2 and Tables 3, 4 and 5 present the results obtained by applying equation (1) to the biomass data generated by Pauly and Palomares (this vol.). The estimates of parental biomass in Fig. 2 resemble those published earlier by Pauly and Soriano (1987). As was the case earlier, the lone independent estimate of parental biomass obtained for August/September 1981 using the egg production method (Santander et al. 1984) is very close to our estimates of parental biomass for that period (see also Table 3, footnote).

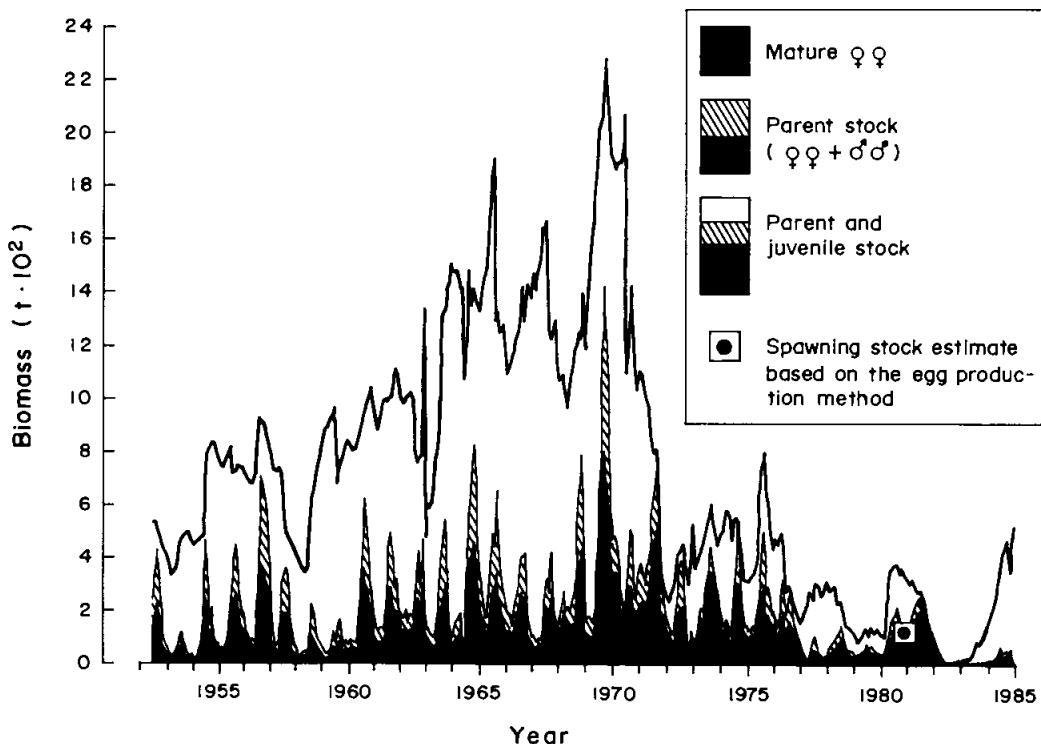

Fig. 2. Total biomass, parent (=mature) stock and biomass of mature female anchoveta off Peru (4-14°S), January 1953 to July 1985. Note strong, regular seasonal oscillations and very good match with independent spawning stock estimate in August/ September 1981 by Santander et al. (1984).

Fig. 2. Biomasa total, stock de padres (=maduros) y biomasa de anchovetas hembras maduras frente al Perú (4-14°S), Enero 1953 a Julio 1985. Notar la fuerte y regular oscilación estacional y una muy buena concordancia con la estimación independiente del stock desovante en Agosto/Septiembre 1981 de Santander et al. (1984).

Table 3. Estimated biomass of mature female and male anchoveta (*Engraulis ringens*) off Peru (4-14°S), January 1953 to July 1985 (in tonnes). Note that estimates for the early/mid-1970s tend to be biased upward (see text).*

Tabla 3. Biomasa estimada de anchovetas maduras (*Engraulis ringens*) hembras y machos frente al Perú (4-14°S), Enero 1953 a Julio 1985 (en toneladas). Notar que los valores para comienzos y mediados de 1970 tienden a estar sobreestimados (ver texto).

*The mean of the values for August and September is $(1434416 + 1160744)/2 = 1.297580$, or 1.3×10^6 tonnes, very close to the independent estimate of 1.2×10^6 tonnes of Santander et al. (1984).

Table 4. Estimated biomass of mature female anchoveta (*Engraulis ringens*) off Peru (4-14°S), January 1953 to July 1985 (in tonnes). Note that estimates for the early/mid-1970s tend to be biased upward (see Table 3 and text).

Tabla 4. Biomasa estimada de anchovetas (*Engraulis ringens*) hembras maduras frente al Perú (4-14°S), Enero 1953 a Julio 1985 (en toneladas). Notar que los valores para comienzos y mediados de 1970 tienden a estar sobreestimados (ver Tabla 3 y texto).

However, the parental biomass estimates, and hence, the estimates of reproductive output for some months (especially during the early 1970s), are different from the values than would have been estimated based on available independent estimates of biomass (Pauly and Palomares, this vol.). Thus, in order for our estimates of egg mortality to be as accurate as possible, we have replaced, in Table 6, the VPA-based estimates of parental biomass (and reproductive output) by proportionally adjusted independent biomass estimates (and by the corresponding estimate of the reproductive output, respectively) in all cases when two biomass estimates for the same month differed by more than 5%. The adjusted estimates are given in brackets in Table 2.

The Evidence for Egg Cannibalism in Anchoveta

Fig. 3A presents a plot of $\ln(N/(D \cdot P))$ vs. parental stock size (P) for the period 1964 to 1985. As might be seen, there is a strong negative correlation between the egg survival index ($\ln(N/(D \cdot P))$) and parent stock, suggesting a strong impact of parental stock on egg mortality rate. This confirms an earlier plot of Santander (1987) based on maps covering the period 1964 to 1982 and on the parental biomass estimates of Pauly and Soriano (1987).

However, parental biomass is not the only factor affecting anchoveta egg survival, and we have derived, to illustrate this, the model:

$$\ln(N/(D \cdot P)) = 33.23 - 2.15 \log_{10} P - 2.50 T + 0.063 T^2 \quad \dots (7)$$

where T is the SST in °C and where $R^2 = 0.594$ (see also Fig 3B and Table 6). Fig. 4 shows that the residuals of this model lack structure, as required for multiple linear regression. Equation (7), it must be realized, is only one of the many possible models, and should not be taken as representing final identification of factors affecting anchoveta egg survival.

Interesting here is Fig. 5 which shows the dependent variable of equation (7) as a function of temperature. As might be seen, some curvature is apparent, as implied by the significant squared term in equation (7).

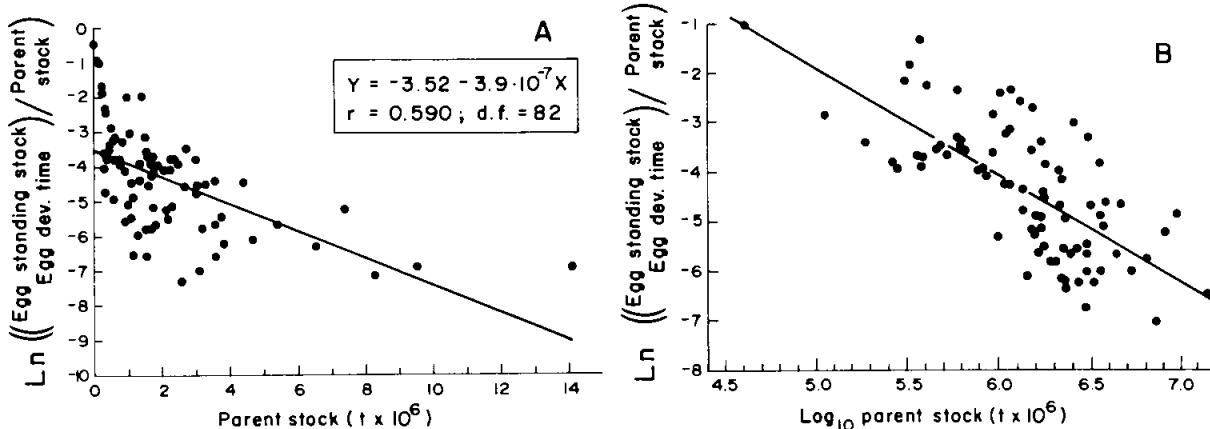

Fig. 3. Evidence of density-dependence in anchoveta egg survival.

A. Bivariate plot, as used to derive Ricker-type stock-recruitment relationships.

B. Plot of the residuals of equation (7) vs. the line linking the index of egg survival (Y-axis) and parental stock. Note markedly improved fit over Plot A, resulting from the inclusion of SST and SST² as variables (see text).

Fig. 3. Evidencia de la densodependencia en la sobrevivencia de huevos de anchoveta.

A. Ploteo bivariado, tal como es usado para derivar la relación stock-reclutamiento de Ricker.

B. Ploteo de residuales de la ecuación (7) vs la línea que relaciona el índice de sobrevivencia de huevos (eje Y) y el stock de padres. Notar el mejor ajuste en relación al ploteo A, a consecuencia de la inclusión de TSM y TSM² como variables (ver texto).

Table 6. Statistics of multiple regression linking anchoveta egg survival index and its predictor variables (equation 7; degrees of freedom = 80, R = 0.771).

Tabla 6. Datos estadísticos de la regresión múltiple que relaciona el índice de sobrevivencia de huevos de anchoveta y sus variables predictoras (ecuación 7; grados de libertad = 80; R = 0.771).

| Variables | (Units) | Estimates | Standard errors ^a |
|--------------------------------|---------------------------------------|------------------------|------------------------------|
| ln (N/(D·P)) | (eggs 10 ⁹ /days · tonnes) | (independent variable) | 0.952 |
| log ₁₀ parent stock | (tonnes) | -2.147 | 0.257 |
| Sea surface temp (SST) | (°C) | -0.250 | 0.942 |
| (SST) ² | (°C) ² | 0.0627 | 0.0245 |

^a Standard error of Y-estimate

Taking the partial derivative of equation (7) with respect to temperature:

$$\frac{\delta \ln (N/(D \cdot P))}{\delta T} = 2(0.0663)T - 2.50 \quad \dots 8)$$

and setting it equal to zero allows estimation of the temperature (T_{min}) at which $\ln (N/(D \cdot P))$ is minimum, i.e., $T_{min} = 19.8^\circ\text{C}$.

Thus, our analysis of Santander's maps provides evidence for:

i) parental cannibalism on anchoveta eggs; and

ii) a parabolic relationship between egg mortality and SST, with maximum close to the upper limit of the optimal temperature range of anchoveta (about 15-20°C).

One multiple regression model we derived, using the data in Table 2, to explain variability of our estimates of egg mortality, is:

$$\log_{10} Z_{egg} = -23.7 + 0.608 \log_{10} P + 0.379 \log_{10} S + 0.505 A_T + 2.4 T - 0.0751 T^2 \quad \dots 9)$$

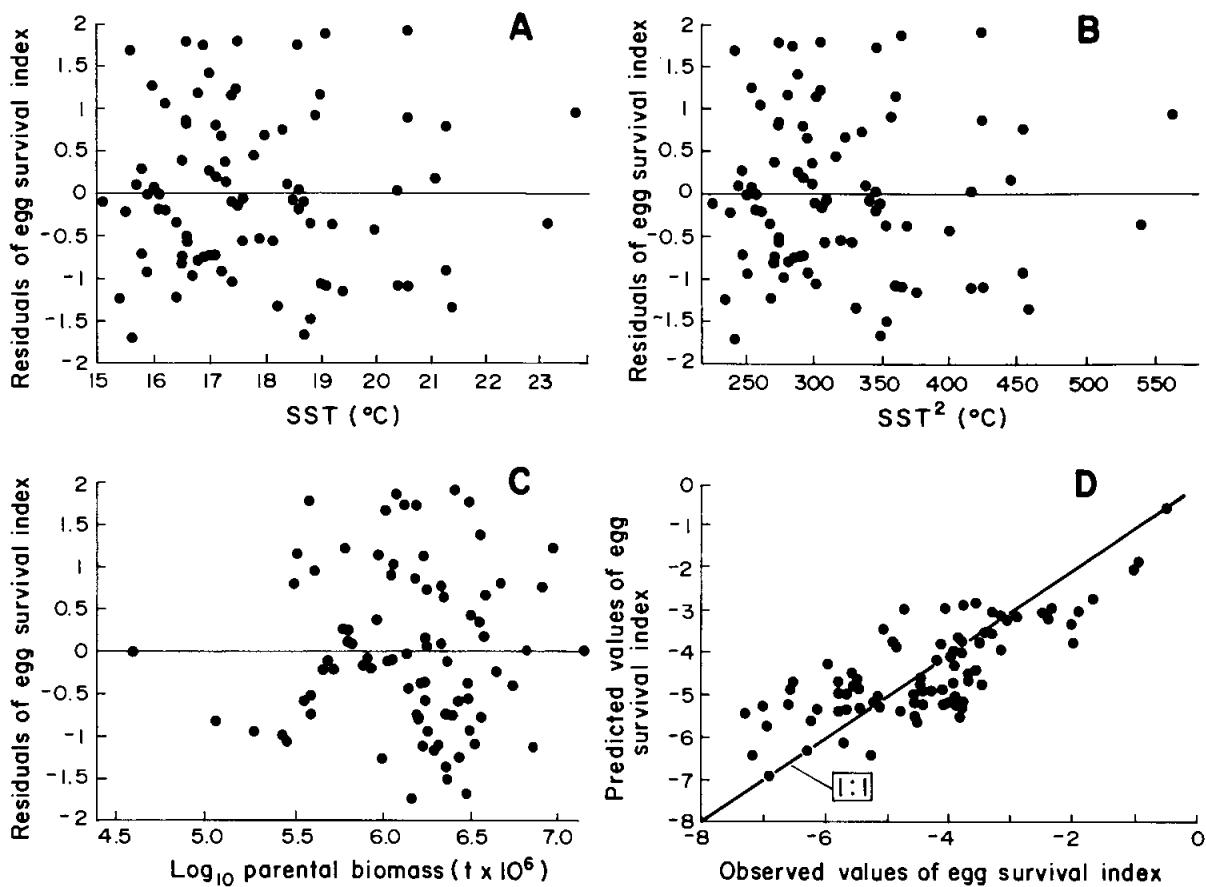

Fig. 4. Selected features of model represented by equation (7). A-C: residuals of equation (7) linking egg survival index and its predictor variables. Note absence of structure. D: plot of observed vs predicted values of the egg survival index.

Fig. 4. Características seleccionadas del modelo representado por la ecuación (7). A-C: residuales de ecuación (7) relacionando el índice de sobrevivencia de huevos y sus variables predictivas. Notar la ausencia de estructura. D: ploteo de valores observados vs valores predictivos del índice de sobrevivencia de larvas.

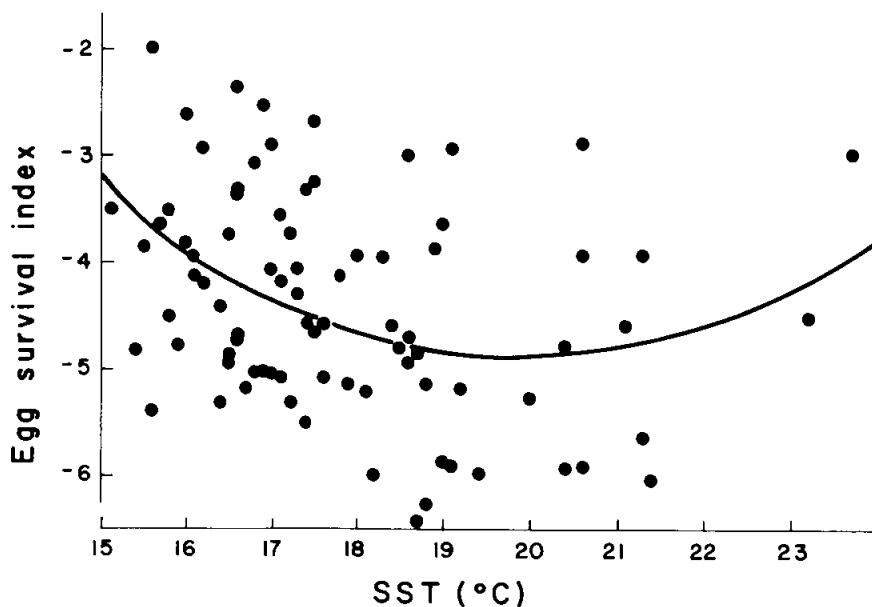

Fig. 5. Relationship of egg survival index and SST; note curvature, suggesting a minimum at 19.8°C .

Fig. 5. Relación entre el índice de sobrevivencia de huevos y TSM; notar curvatura, sugiriendo un mínimo a 19.8°C .

which has an $R^2 = 0.562$ and whose statistics are given in Table 7. Fig. 6 shows that this model gives a particularly good fit to SST and SST anomaly, and a lesser fit to the biological variables (parent stock and sardine stock). Again, SST has a parabolic relationship with egg mortality. Taking the partial derivative of equation (9) with respect to T gives:

$$\frac{\delta \log_{10} Z_{\text{egg}}}{\delta T} = 2.4 - 2(0.0751) T \quad \dots 10)$$

which set equal to zero and solved for T gives $T_{\max} = 16.0^{\circ}\text{C}$.

Thus, we find again that anchoveta egg mortality has a peak within the range of temperature that is optimal for anchoveta.

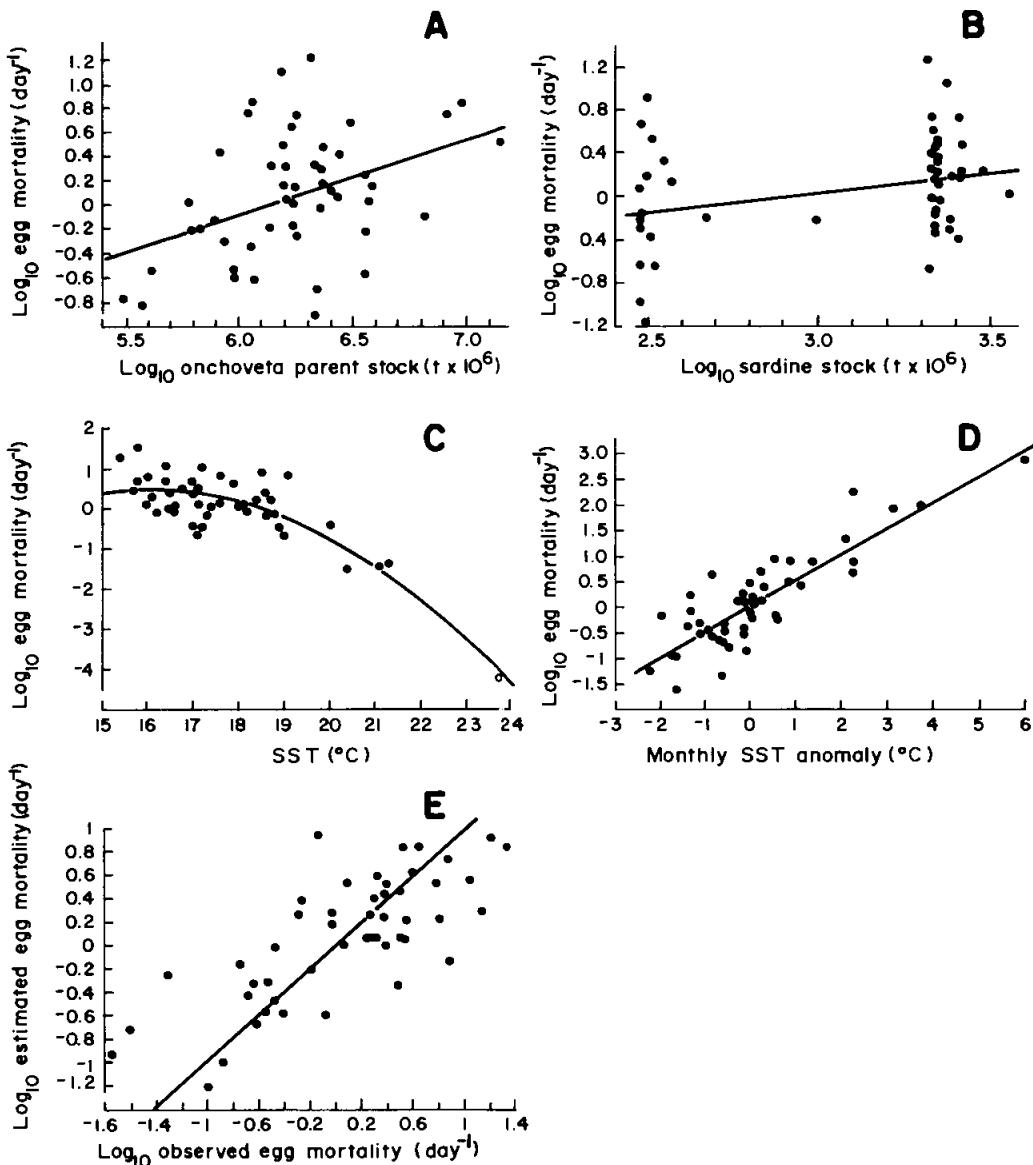

Fig. 6. Relationship between anchoveta egg mortality and its predictor variables. The solid lines of Plots A-D represent the axes of equation (9), with intercepts set at the mean of all other variables; the dots represent the residuals, plotted from the solid lines. Plot E shows the predicted vs. the observed mortalities. Note overall good fit of equation (9) to the data, the absence of structure in the residuals, and the strong relationship between mortality, SST and SST anomaly.

Fig. 6. Relación entre la mortalidad de huevos de anchoveta y sus variables predictoras. Las líneas sólidas de los ploteos A-D representan el eje de la ecuación (9), con interceptos fijados al promedio de todas las otras variables; los puntos representan los residuos, pleteados de las líneas sólidas. El Ploteo E muestra la mortalidad estimada vs la observada. Notar el buen ajuste general de la ecuación (9) a los datos, la ausencia de estructura en los residuos y la fuerte relación entre mortalidad, TSM y la anomalía de TSM.

Table 7. Statistics of equation (9), relating anchoveta egg mortality and its predictor variables (degrees of freedom = 43; R = 0.751).

Tabla 7. Datos estadísticos de la ecuación (9), que relaciona la mortalidad de huevos de anchoveta y sus variables predictoras (grados de libertad = 43; R = 0.751).

| Variables | (Units) | Estimates | Standard errors ^a |
|---------------------------------|----------------------|-------------------|------------------------------|
| log ₁₀ egg mortality | (day ⁻¹) | (indep. variable) | 0.4937 |
| log ₁₀ parent stock | (tonnes) | 0.6078 | 0.2851 |
| log ₁₀ sardine stock | (tonnes) | 0.3788 | 0.2160 |
| SST anomaly (AT) | (°C) | 0.5049 | 0.0758 |
| Sea surface temp. (SST) | (°C) | 2.4007 | 0.6881 |
| (SST) ² | (°C) ² | -0.0751 | 0.0185 |

^a Standard error of Y-estimate.

Fig. 6D, which shows the *positive* partial correlation between anchoveta egg mortality and SST anomaly, suggests, however, that the observed parabolic relationship between SST and egg mortality do not reflect a causal linkage. Rather, SST, which fluctuates seasonally, is lowest in September-October (see Fig. 8 and Bakun 1987), during a period when anchoveta concentrate under the coast for spawning (Jordán 1971; FAO 1981; Csirke, this vol.).

Anchoveta feed during the spawning season and hence, the peak consumption of anchoveta eggs by adult anchoveta occurs in September-October (Fig. 7; Table 8). This could explain the apparent relationships between SST and egg mortality. As for SST anomaly, we assume that it is linked with anchoveta egg mortality via two mechanisms: (1) increased predation on anchoveta eggs by zooplankton and other predators not included in our models, and whose metabolic rate and hence, food consumption, can be expected to increase when the SST anomaly increases and (2) increased concentration of anchoveta within the small inshore patches of low SST waters that remain during high SST anomalies (Muck et al., this vol.).

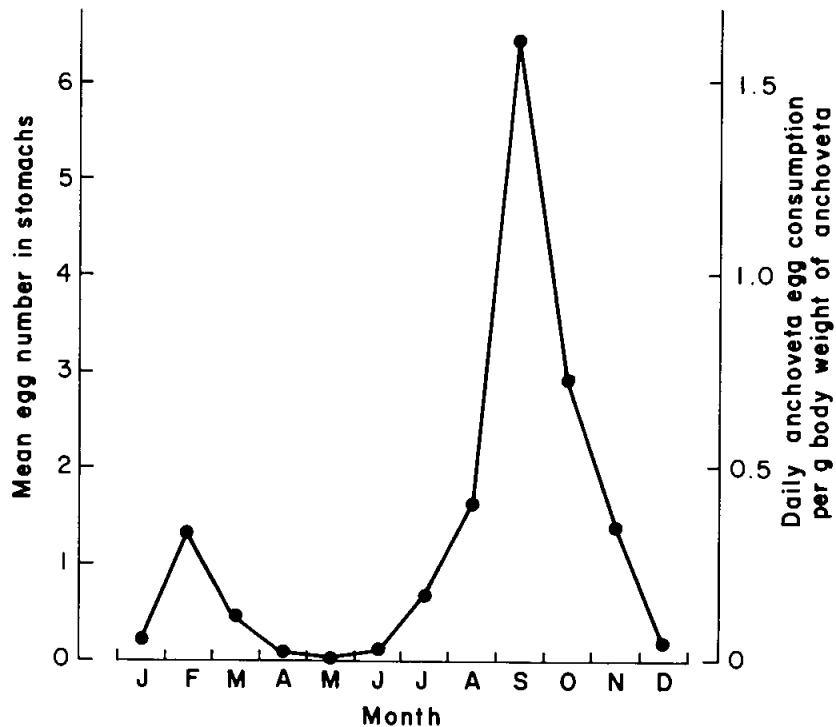

Fig. 7. Mean number of anchoveta eggs in the stomach of anchoveta sampled from 1953 to 1982 by Rojas de Mendiola (this vol.) and Alamo (this vol.), as extracted from their database (see Table 8 for details). Note strong seasonality, with a major peak during the major spawning season (September/October) and a minor peak during the minor spawning season (February/March). The scale on the right side provides an approximate conversion to egg consumption rate (see Table 8).

Fig. 7. Número promedio de huevos de anchoveta en el estómago de anchoveta muestrada de 1953 a 1982 por Rojas de Mendiola (este vol.) y Alamo (este vol.), extraído de su base de datos (ver tabla 8 para detalles). Notar la fuerte estacionalidad, con un pico mayor durante la estación de desove principal (Septiembre/Octubre) y un pico menor durante la estación de menor desove (Febrero/Marzo). La escala del lado derecho proporciona una conversión aproximada de la tasa de consumo de huevos (ver Tabla 8).

Equation (9) predicts, for anchoveta eggs in August/September 1987, a value of $Z = 2.13 \text{ day}^{-1}$; this is much higher than the value of 0.91 day^{-1} presented by Santander et al. (1984).

Data are available which might allow resolving this discrepancy, and testing of the hypotheses presented above. Notably, a detailed analysis of the Rojas/Alamo database on anchoveta stomach contents emphasizing seasonal and interyear variations of egg cannibalism (i.e., going beyond the mean seasonal cycle in Fig. 8), and combined with corresponding estimates of anchoveta concentration, could contribute toward elucidating the role of egg cannibalism in anchoveta population dynamics.

Table 8. Data for quantification of egg cannibalism in anchoveta, as extracted from the Rojas/Alamo database (see Rojas de Mendiola, this vol.; Alamo, this vol.; Pauly et al., this vol.).

Tabla 8. Datos para la cuantificación del canibalismo de huevos de anchoveta, extraídos de la base de datos de Rojas/Alamo (ver Rojas de Mendiola, este vol.; Alamo, este vol.; Pauly et al., este vol.).

| Month | No. of anchoveta with sampling month and record for eggs | No. of anchoveta with eggs in the stomach | Total no. of eggs in stomach | Mean eggs per anchoveta stomach | Daily Anchoveta egg consumption ^a |
|-----------|--|---|------------------------------|---------------------------------|--|
| January | 616 | 38 | 126 | 0.205 | 0.051 |
| February | 769 | 77 | 1000 | 1.300 | 0.325 |
| March | 852 | 22 | 379 | 0.445 | 0.111 |
| April | 633 | 17 | 60 | 0.095 | 0.024 |
| May | 409 | 7 | 17 | 0.042 | 0.010 |

| September | 1698 | 520 | 10935 | 6.440 | 1.610 |
| October | 869 | 99 | 1664 | 1.915 | 0.479 |
| November | 1057 | 112 | 1469 | 1.390 | 0.348 |
| December | 971 | 53 | 188 | 0.194 | 0.048 |

^a Approximate daily anchoveta egg consumption per g body weight of anchoveta (see also Fig. 7), as computed from the daily ration of 0.448 g estimated by Pauly et al. (this vol.) for anchoveta of about 20 g live weight, and a mean stomach content of 0.122 g. The quotient of mean stomach content over ration is ≈ 3.7 , but this estimate of turnover rate was increased to 5 to account for the facts that (1) most stomachs with eggs were sampled early mornings, when stomach contents are less than average and (2) that eggs are more rapidly digested than other food items.

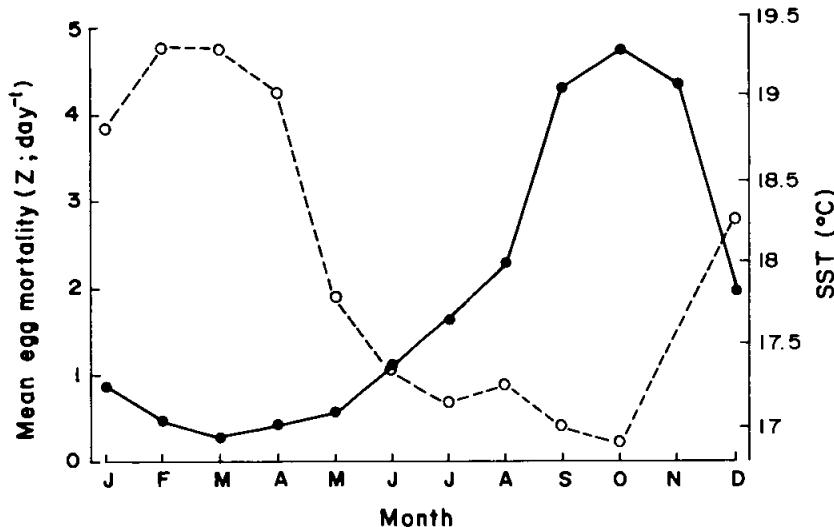

Fig. 8. Solid line: annual cycle of mean monthly anchoveta egg mortality, 1964 to 1985, based on map-specific Z values in Table 2, or on estimates from equation (9) when these could not be computed via equation (6); monthly means were smoothed over 3 months. Note strong summer peak, coincident with peak occurrence of eggs in anchoveta stomachs (see Fig. 7). Dotted line: mean seasonal cycle of sea surface temperature, as derived using only SST values for the months represented in Table 2, and smoothing over 3 months.

Fig. 8. Línea sólida: ciclo anual del promedio mensual de la mortalidad de huevos de anchoveta, 1964 a 1985, basado en valores de Z obtenidos de mapas específicos de la Tabla 2, o en estimaciones de la ecuación (9) cuando éstos no pudieron ser computados por la ecuación (6); los promedios mensuales fueron suavizados mediante promedio corrido de 3 meses. Notar el fuerte pico de verano, coincidente con la ocurrencia del pico de huevos en los estómagos de anchoveta (ver Fig. 7). Línea interrumpida: ciclo estacional promedio de la temperatura superficial derivado usando solo valores de TSM para los meses presentados en la Tabla 2, y suavizados con promedios corridos de 3 meses.

Abstract

Time series of sea surface temperature (SST) of nine shore stations along the entire Peruvian coast ($4-17^{\circ}\text{S}$), available on a monthly basis for the period 1950-1988, were analyzed with reference to the spatial and temporal variability of SST and related standard deviation, and discussed with regard to the spawning strategies of the Peruvian anchoveta (*Engraulis ringens*).

Resumen

Se presenta un análisis de las series de tiempo de la temperatura superficial del mar (TSM) para nueve estaciones costeras del Perú ($4-17^{\circ}\text{S}$) para el período 1950-1988. Los resultados son analizados con respecto a la variabilidad temporal y local de la TSM y su respectiva desviación estandar, y es discutido con respecto a las estrategias de desove de la anchoveta (*Engraulis ringens*).

Introduction

Time series of spatial means of sea surface temperature (SST) for the area $4-14^{\circ}\text{S}$ have been reported in Pauly and Tsukayama (1987) and Bakun (1987), and have become important information for modelling purposes (e.g., Muck and Pauly 1987; Muck and Fuentes 1987; Muck and Sanchez 1987; Muck a, b, this vol.; Muck et al., this vol.; Mendo et al., this vol.; Pauly and Soriano, this vol.).

Priority is given in these studies to the analyses of temporal changes in SST (seasonality, El Niño events) expressed as mean values for the whole area ($4-14^{\circ}\text{S}$). However, little has been reported on the spatial (e.g., north-south) distribution of SST and the temporal and spatial variability of that distribution.

SST provides information on physical conditions of the ecosystem (temperature, upwelling, turbulence, primary production, see e.g., Medina (1979); Enfield (1981); Muck et al. (1987); Mendo et al. (this vol.)). On the other hand, the SST-standard deviation (SST-SD) of a number of simultaneous (monthly) measurements of SST values taken along the coast refers to its stochastic nature.

It might be the latter one which determines the degree of distinctness in evolutionary adaptations of life cycle strategies.

Data Acquisition

The monthly SST time series analyzed here, pertaining to nine shore stations, cover a period of 38 years (1950-1988) and are documented in Muck et al. (1989).

The nine shore stations are: Talara ($04^{\circ}34'S$); Paita ($05^{\circ}05'S$); Puerto Chicama ($07^{\circ}43'S$); Chimbote ($09^{\circ}05'S$); Don Martín ($11^{\circ}02'S$); Callao ($12^{\circ}04'S$); Pisco ($13^{\circ}40'S$); San Juan ($15^{\circ}21'S$); and Ilo ($17^{\circ}38'S$).

The missing values in the original data set (= 24%, referring almost exclusively to the first decade (1950-1960)) were linearly interpolated by Muck et al. (1989) in all cases where only one or two months were missing, or estimated by linear regression between the time series of neighboring stations when the missing sequence was of three months or more (Muck et al. 1989). The SST-SD values used throughout this contribution express the standard deviation of the nine measurements available for each month from 1950 to 1988.

Diskette 1 (see Appendix I) provides the uncorrected SST time series for the nine shore stations.

Results and Discussion

The SST-anomalies derived from the data presented above show the typical oscillation between abnormally warm periods (El Niño events) and abnormally cold periods. Between 1950 and 1987, there were five periods with positive anomalies $>1^{\circ}\text{C}$, eight periods with positive anomalies $>0.5^{\circ}\text{C}$, five periods with negative anomalies $<-0.5^{\circ}\text{C}$ and one period with a negative anomaly $<-1^{\circ}\text{C}$ (Fig. 1).

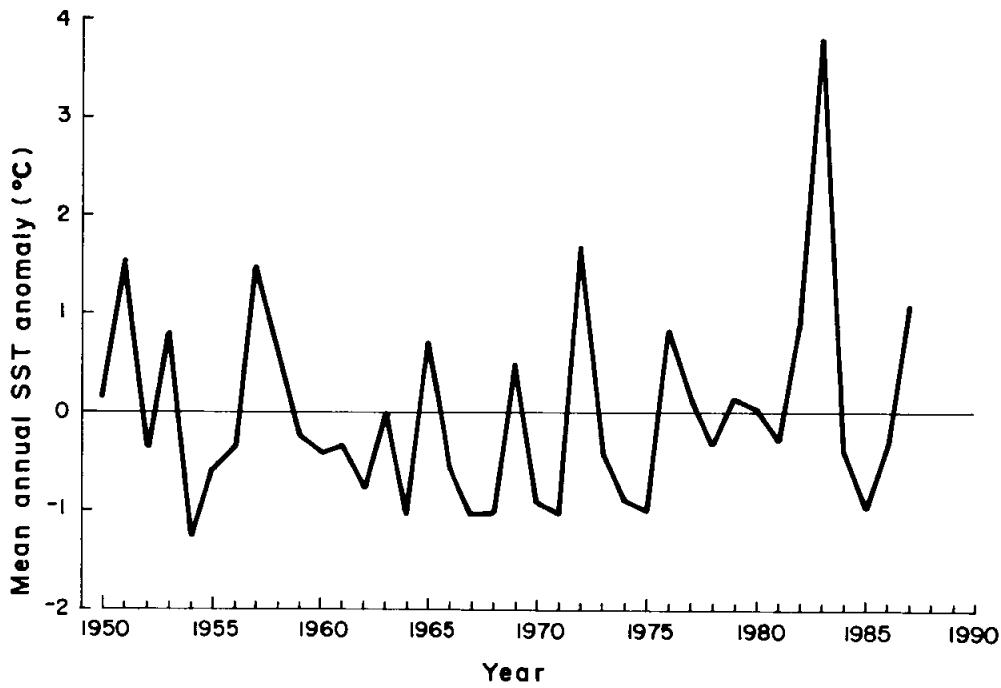

Fig. 1. Time series of mean annual sea surface temperature anomaly off Peru, 1950-1987.

Fig. 1. Serie de tiempo de los promedios anuales de anomalías de la temperatura superficial del mar frente a Perú, 1950-1987.

The curve of the annual anomaly of the SST-SD-values (Fig. 2) shows a pattern similar to that of Fig. 1: years with SST-anomalies were also years with SST-SD-anomalies. In other words, the differences of SST between the nine shore stations along the Peruvian coast are higher during years with El Niño events than during normal ones, and conversely lower during cold years.

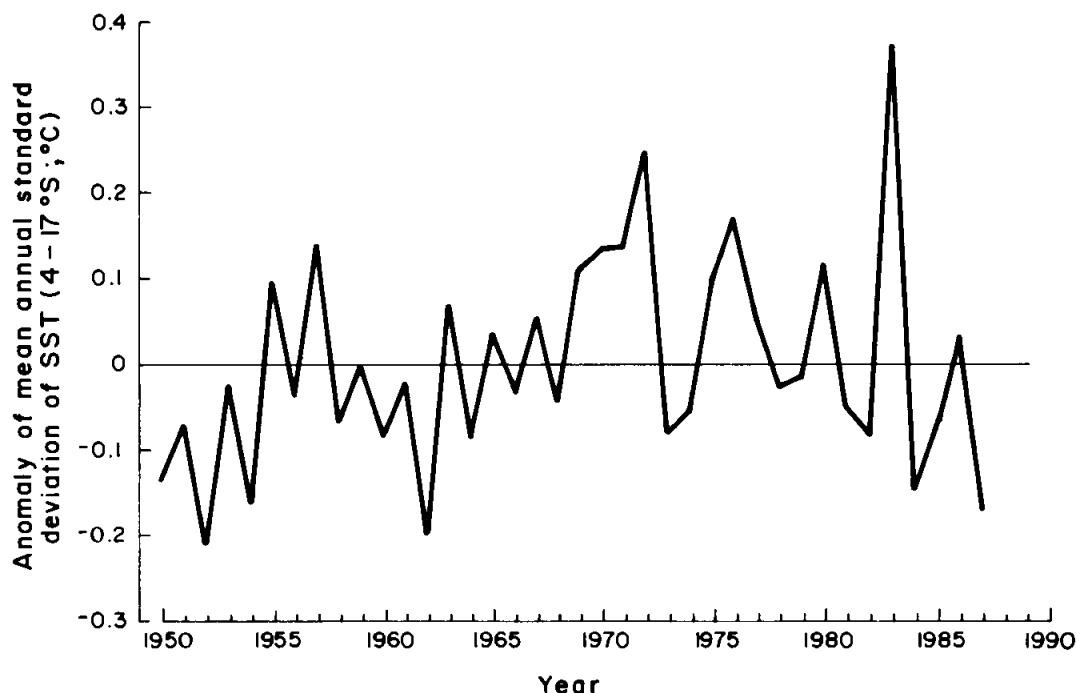

Fig. 2. Time series of anomalies of mean annual standard deviation of sea surface temperature from nine coastal stations off Peru (4-17°S).

Fig. 2. Serie de tiempo de anomalías de los promedios anuales de las desviaciones estandar de la temperatura superficial del mar, en nueve estaciones costeras frente a Perú (4-17°S).

Comparing the curves of Fig. 1 and Fig. 2, it is notable that during the 1972 and 1976 El Niño events, the positive SST-SD-anomalies occur well before the SST-anomalies.

Indeed, a detailed analysis of the spatial and temporal pattern of SST-anomalies during the very strong El Niño in 1982-1983 shows a clear north-south propagation of SST-anomalies and also shows that the maximum SST-anomaly occurs in the south of Peru (near San Juan-Ilo) about three months later than in the north (near Talara-Paita).

Plotting the mean monthly SST-SD-values from 4-17°S, we obtain Fig. 3, which shows clearly two periods with different regimes: a period of very high SST-SD-values between April and July (autumn, early winter) and a longer period of low SST-SD between August and March (mid-winter, spring, summer).

Low values of monthly SST-SD means that during the 38 years covered here, the temperature variations within a given month were low (=high stability). Thus, the spatial mean of all monthly SST-SD-values in Fig. 3 can be interpreted as an index of the spatial homogeneity of SST. In other words, the high values of the mean monthly SST-SD occurring in May and June indicate low spatial homogeneity of SST, while the very low SST-SD-values during August-October suggest that during this period, the whole area covered here (4-17°S) has very similar characteristics (i.e., is very homogeneous).

Thermal variability can be assumed to reflect the dynamics of other physical properties of the pelagic ecosystem such as upwelling, turbulence, primary production, and depth of the mixed layer. Thus, generalizing my interpretation of the dynamics of SST-SD, I suggest that the curve given in Fig. 3 expresses changes from periods of environmental stability to periods of environmental perturbations, or with reference to the communities within the ecosystem, from periods of low to periods of high environmental uncertainty.

When comparing Fig. 3 with Fig. 7 in Pauly (1987) on the seasonal cycle of anchoveta spawning behavior, I found a surprising coincidence: maximum spawning activity (October) generally falls in the month with the lowest environmental perturbations and almost no spawning occurs during May-June, when the SST-SD-values are highest. The same match is found when one compares the second smaller spawning peak of February-March with the corresponding SST-SD-values.

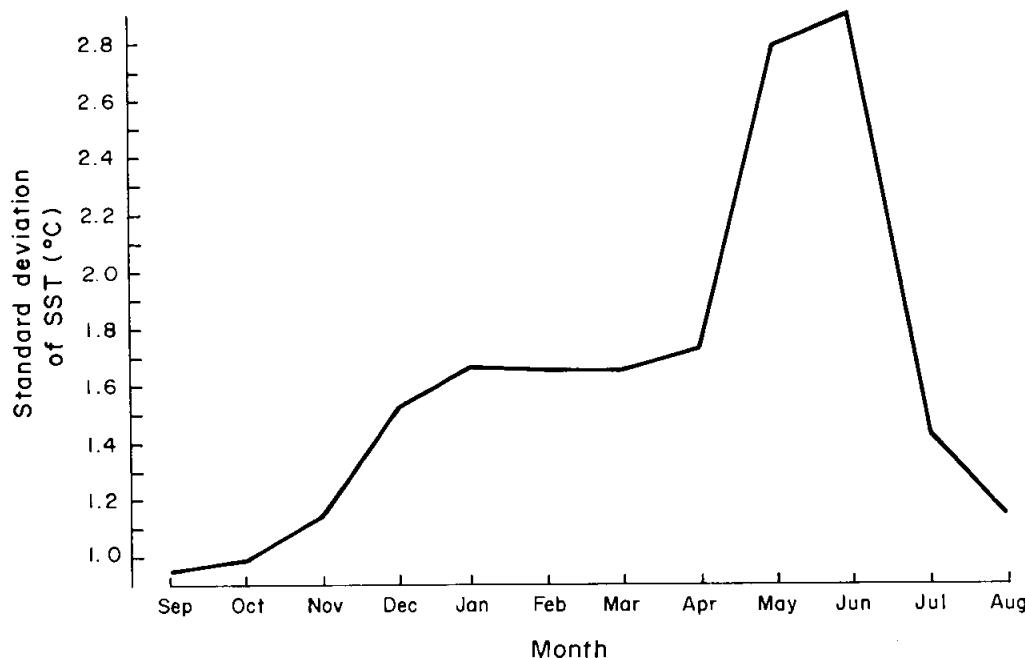

Fig. 3. Mean standard deviation of SST between nine coastal stations off Peru (4-17°S), monthly averages based on data for the years 1950 to 1987. High values suggest lack of homogeneity along the coast and hence low predictability of reproductive success. Note low values during August-November, i.e., the major spawning season of anchoveta.

Fig. 3. Promedios de desviaciones estandar de la TSM en nueve estaciones costeras frente a Perú (4-17°S), promedios mensuales basados en datos de los años 1950 a 1987. Los altos valores sugieren falta de homogeneidad a lo largo de la costa y por lo tanto bajo poder de predicción del éxito reproductivo. Nótese los bajos valores durante Agosto-Noviembre, es decir, durante la estación principal de desove de anchoveta.

Plotting monthly data of the fraction of mature females from Callao and Chimbote samples (Jordan 1980, in Pauly and Soriano 1987) vs. the SST-SD for these areas (Table 1) led to Fig. 4. This indicates a strong negative correlation between the percentage of mature females in catch samples and the values of SST-SD for the corresponding months.

I interpret these findings as an expression of a long-term evolutionary adaptation of anchoveta spawning to seasons with different environmental uncertainty: the main spawning event occurs during periods when there is a high probability that environmental conditions will be "as always" (i.e., differing little from the long-term mean values).

While seasonal spawning peaks occur, it must also be noted that some anchoveta spawn throughout the year. Paulik (1981) wrote on this:

"The anchoveta, with 2- or 3-year classes in its population, cannot afford the luxury of gambling on the weather. Lack of spawning success in a single year could be disastrous. So anchoveta hedges its bet by spawning over the entire year and increasing its chances of encountering favorable conditions during some part of the extended spawning season".

Thus, the question arises: Are there two different spawning strategies of two genetically different anchoveta (sub)populations, one spawning mainly from September to November, the other throughout the year?

Fig. 5 shows the trend of October values of SST-SD (i.e., during the main spawning season) from 1950 to 1987. In this graph, low SST-SD-values imply that spawning in October was the "right" thing to do, while high values of SST-SD indicate that spawning over the whole year was the better strategy. As might be seen, this graph suggests that from the mid-1960s to the mid-1980s, spawning over the whole year was the better strategy. This should have led to a reduced fitness of the fish adapted to spawning mainly from September to November, and hence to a reduction of their proportion in the overall population, relative to anchoveta with a tendency to spawn year-round. The findings of Senocak et al. (this vol.) support this hypothesis.

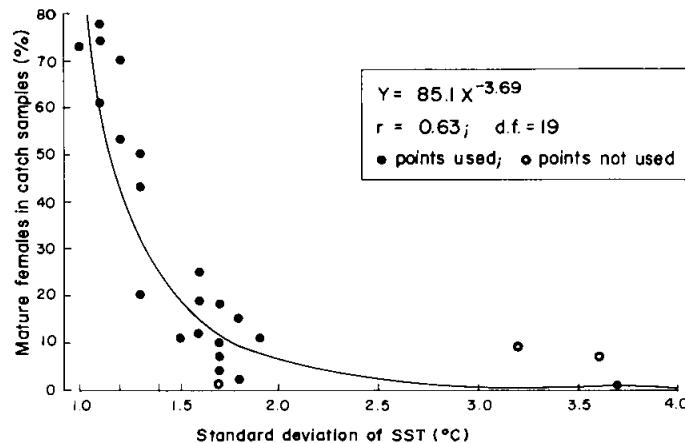

Fig. 4. Relationship between the relative abundance of mature female anchoveta in catch samples (Callao, Chimbote) and the standard deviation of mean monthly SST for these locations (see text for data sources).

Abstract

Marking experiments were conducted with fingerlings of anchoveta (*Engraulis ringens*), sardine (*Sardinops sagax*), silversides (*Odontesthes regia*) and Atlantic menhaden (*Brevoortia tyrannus*) using tetracycline baths or injections, or through feeding the experimental fish with *Artemia salina* previously held in tetracycline. The resulting marks on otoliths, scales and vertebrae are clearly visible in ultraviolet light, stable under long-term storage conditions, and hence can serve for validation of age and growth studies or for aging of tropical fishes. Data to estimate the relationships between mark visibility, fish mortality and dosage are given for three of the investigated fish species.

Resumen

Se han realizado experimentos de marcación de juveniles de anchoveta (*Engraulis ringens*), sardina (*Sardinops sagax*), pejerrey (*Odontesthes regia*) y Atlantic menhaden (*Brevoortia tyrannus*) usando baños o inyecciones de tetraciclina o a través de experimentos de alimentación con *Artemia salina*, previamente marcada con tetraciclina. Las marcas resultantes en otolitos, vértebras y escamas son claramente visibles en luz ultravioleta, estables y con capacidad de almacenamiento de larga duración, y por lo tanto sirven para validar estudios de edad y crecimiento o para estimar la edad de peces tropicales. Datos para la estimación de la relación entre visibilidad de marcas, mortalidad de peces y dosis son dados para tres de las especies de peces investigados.

Introduction

The antibiotic known as tetracycline can be used to mark vertebrate bones. Marked bone tissues fluoresce in golden yellow, whereas unmarked bones show only a weak, pale blue fluorescence (Harris 1960). Thus, tetracycline can be used to resolve problems associated with age validation of temperate/cold water fishes (Beamish and McFarlane 1983) or with aging of tropical species.

Example of studies based on these techniques are those of Weber and Ridgway (1962) on sockeye salmon (*Oncorhynchus nerka*), king salmon (*Oncorhynchus tshawytscha*) and rainbow trout (*Salmo gairdneri*), Kobayashi et al. (1964) on *Carassius auratus*, Jones and Bedford (1968) on *Gadus morhua*, Holden and Vince (1973) on *Raja clavata*, Casselman (1974) on *Esox lucius*, Nagiec et al. (1983) on *Coregonus lavaretus*, Smith (1984) on *Triakis semifasciata*, and Dekker (1986) on *Anguilla anguilla*. Unpublished experiments were also conducted in 1970 on anchoveta (*Engraulis ringens*) by A. Málaga of IMARPE, Perú and K.M. Wilbur of Duke University, USA. Table 1 summarizes data from some of these studies. As might be noted, they usually do not indicate the optimal dose for marking the species studied.

Table 1. Tetracycline doses used in various fish marking studies.

Tabla 1. Dosis de tetraciclina usada en varios estudios de marcación de peces.

| Species | Source | Type of tetracycline | Doses (mg/g fish) | Medium |
|--------------------------|---------------------------------|----------------------------|-------------------|-------------------|
| <i>Engraulis ringens</i> | Málaga and Wilbur (unpublished) | Acromicyn | 0.8 | Seawater |
| <i>Gadus morhua</i> | Jones and Bedford (1968) | Acromicyn | 0.025 | Saline solution |
| | | | 0.05 | Saline solution |
| | | | 0.1 | Saline solution |
| <i>Esox lucius</i> | Casselman (1974) | Tetracycline hydrochloride | - | - |
| <i>Raja clavata</i> | Holden and Vince (1973) | Tetracycline hydrochloride | 0.05 | Isotonic solution |
| | | | 0.1 | Isotonic solution |
| <i>Carassius auratus</i> | Kobayashi et al. (1964) | Acromicyn | 0.05 | Isotonic solution |
| | | | 0.1 | Isotonic solution |

A strong dose of tetracycline usually results in mortality and in a wide and diffuse band, whose central area, corresponding to the exact time of marking, is difficult to locate. Small doses, on the other hand, result in marks (rings) that are difficult to detect; these doses, however, protect the fish against infections associated with the insertion of, e.g., individual tags. In this study, therefore, a wide range of doses were administered to enable identification of the optimum dosage.

Materials and Methods

The marking experiments reported upon here were conducted on 240 juvenile individuals of four species and three families of pelagic fishes: anchoveta (*Engraulis ringens*, Fam. Engraulidae), sardine (*Sardinops sagax*, Fam. Clupeidae), Atlantic menhaden (*Brevoortia tyrannus*, Fam. Clupeidae) and silverside (*Odontesthes regia*, Fam. Atherinidae).

These experiments were conducted in Peru in January 1975 and May 1977 with the three Peruvian species, and at the Marine Laboratory of the US National Marine Fisheries Service (NMFS) in Beaufort, North Carolina in May 1976. Some reading and photographing of labelled material were done at the MAFF in Aberdeen, Scotland, in October 1976-April 1977.

The fish used for the experiments were either scooped from commercial purse seines (anchoveta and sardine) or caught with gill nets (silverside and menhaden).

Only fish not affected by netting (i.e., which had survived for 35 days) and which had been feeding actively for at least 20 days were used for the tetracycline marking experiment (Fig. 1). They were kept either in oxygenated 4,000-l tanks, or in floating live boxes anchored off San Lorenzo Island, near Callao, at water temperature of about 15°C. In the latter case, which applied to some anchoveta and silverside, the fish consumed food naturally produced in the boxes. The anchoveta, sardine and silverside in the tanks were fed minced fish flesh supplemented with a commercial fishmeal-based poultry feed, or in some special cases, tetracycline-labelled *Artemia salina*. The menhaden were fed commercial pellets such as generally used at the Beaufort Laboratory of NMFS.

Prior to administration of tetracycline, the individual fish were:

1. exposed, until the respiratory movements slowed down, to a solution of the anesthetic MS 222 (at a concentration of about 1:10,000 in seawater) or of Quinaldine (about one drop per liter of water);
2. measured to the nearest 0.5 cm;

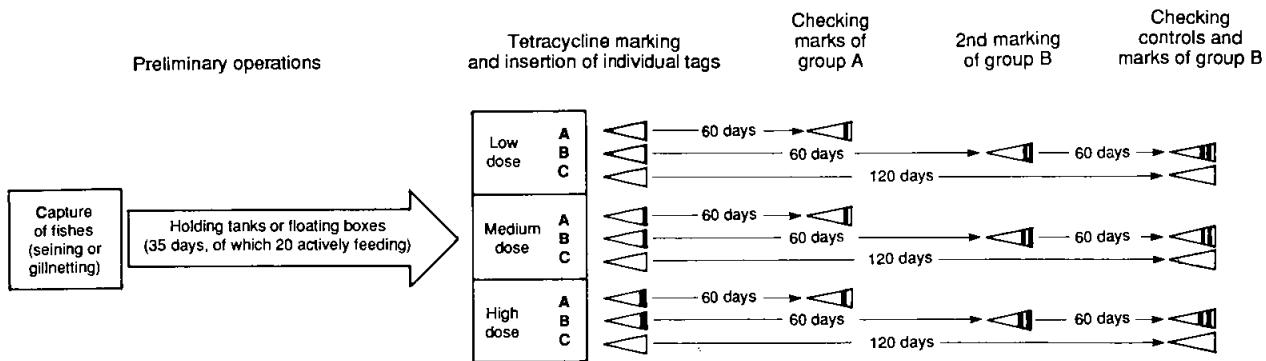

Fig. 1. Schematic representation of the experimental design used for tetracycline marking of anchoveta and other small pelagic fishes. Group A (1 marking) = 25 fish; Group B (2 markings) = 25 fish; Group C (control, no marking) = 10 fish.

Fig. 1. Representación esquemática del diseño experimental usado para la marcación con tetraciclina de la anchoveta y otros peces pelágicos. Grupo A (1 marcación) = 25 peces; Grupo B (2 marcaciones) = 25 peces; Grupo C (control, sin marcación) = 10 peces.

3. weighted to the nearest 0.5 g (the weights were used to compute the required dose of tetracycline);
4. tagged with an individually coded spaghetti tag, inserted into the dorsal muscle just anterior to the first dorsal fin. Internal (magnetic) tags were also inserted into the ventral cavity of anchoveta and sardine.
5. returned to seawater (fish which lost the spaghetti tags administered in (4) were not further considered).

The tetracycline used for the experiments was either chlortetracycline, oxytetracycline or pure tetracycline. No attempts were made to distinguish between possibly different effects of these compounds.

Administration of tetracycline was performed as follows:

- i. through intraperitoneal injection of tetracycline-laced hot gelatin into a spot anterior to the pelvic fin, such as to leave the intestine and liver unharmed by the needle (performed between steps (4) and (5) above in the form of a unique dose (0.005, 0.05 and 0.1 mg/g/fish);
- ii. through a bath in water with 20 mg of tetracycline per liter for periods lasting from 1 to 10 days (as in Hettler 1984);
- iii. force-feeding of pill boxes containing a dose of tetracycline; cumulative doses (0.025-1.000) mg/g fish;
- iv. feeding from 1 to 10 days with adult *Artemia salina* that had been kept for 6 days in tetracycline solution (50 mg/l) after a starvation period of 2 days or with larval *Artemia* that had been hatched in 500 mg/l tetracycline solution.

Marked scales, otoliths and vertebrae were kept for occasional reexamination, to assess the stability of the markings under storage conditions.

Results and Discussion

As illustrated in Fig. 2A with regard to anchoveta, tetracycline-induced mortality depends on dose; a 50% mortality within two weeks after marking is induced by a cumulative dose of 0.63 mg/g, administered over a period of 3-5 days. Visibility of tetracycline markings is also strongly dependent on dosage (see Fig. 2B).

The results for the three other species of fishes investigated here were similar, and are summarized in Table 2. Anchoveta and sardine kept in 50 mg/l tetracycline solution bath as well as those fed with *Artemia* previously immersed in tetracycline solution were the ones with the highest percentage of visible markings. In the case of small menhaden ($\bar{L} = 3.5$ cm, $\bar{W} = 6$ g), a tetracycline bath produced very visible marks while feeding of *Artemia* larvae hatched in tetracycline solution produced only a weak fluorescence.

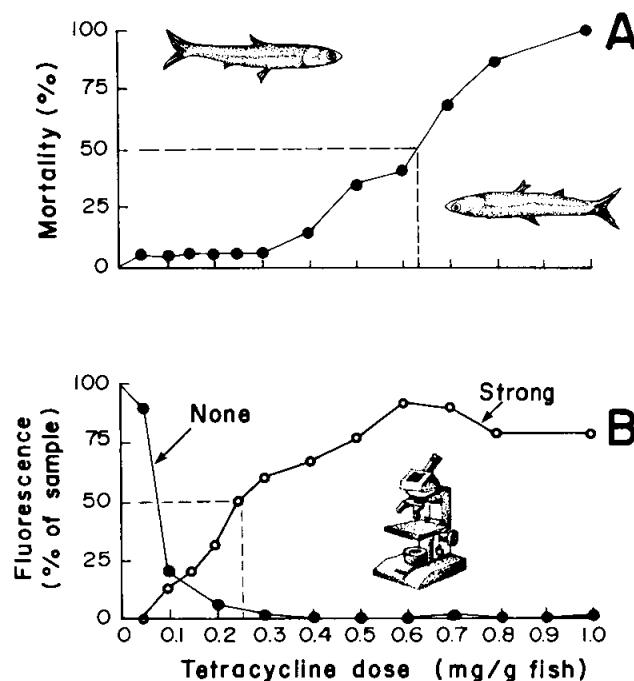

Fig. 2. Response of anchoveta (*Engraulis ringens*) to cumulative tetracycline exposure of 3-5 days (see Table 2 for larger exposures). A. Mortality as a function of dose; 50% mortality occurs at about 0.63 mg/g fish. B. Visibility of marks as a function of dose; 50% of marked samples will have strong marks at a dose of 0.25 mg/g fish.

Fig. 2. Reacción de la anchoveta (*Engraulis ringens*) a la exposición acumulada con tetraciclina por 3-5 días (ver tabla 2 para exposiciones más largas). A. Mortalidad como una función de la dosis; 50% de mortalidad ocurre acerca de 0.63 mg/g pez. B. Visibilidad de las marcas como función de la dosis; 50% de las muestras marcadas tendrán marcas fuertes a la dosis de 0.25 mg/g pez.

Table 2. Relationship between cumulative dose of tetracycline, duration of exposure, mortality and visibility of marks in (A) anchoveta ($\bar{l} = 11.2$ cm; $\bar{w} = 13.0$ g), (B) sardine ($\bar{l} = 14.5$ cm; $\bar{w} = 16.8$ g), and (C) Atlantic menhaden ($\bar{l} = 18.0$ cm, $\bar{w} = 20.0$ g).

Tabla 2. Relación entre la dosis acumulada de tetraciclina, duración de la exposición, mortalidad y visibilidad de las marcas en (A) anchoveta ($l = 11.2$ cm; $w = 13.0$ g), (B) sardina ($\bar{l} = 14.5$ cm; $\bar{w} = 16.8$ g) y (C) Atlantic menhaden ($\bar{l} = 18.0$ cm; $\bar{w} = 20.0$ g).

| Cumulative dose (mg/g fish) | Duration of exposure (days) | Fish mortality (%) A / B / C | Fluorescence (% of sample) | | |
|-----------------------------|-----------------------------|---------------------------------|----------------------------|-------------------|---------------------|
| | | | None A / B / C | Weak A / B / C | Strong A / B / C |

Introperitoneous injection of two different doses of tetracycline (0.05 and 0.1 mg/g) led to small differences in the width of the markings, but the smaller dose is better, because the mortality induced is smaller.

The *Artemia* larvae fed to the experimental fish were all strongly fluorescent. All fish fed for six days with these larvae got fluorescent marking of their hard structures.

Overall, fluorescence occurred in all hard structures (scales, otoliths, vertebrae) of all fish, after 24 hours when they had been injected a dose of 0.5 mg/g or after 48 hours when they had been injected a dose of 0.05 mg/g.

Tetracycline marks on material kept in storage tend to fade, but the process is slow, and marks can be observed on scale, otoliths or vertebrae two years after marking. When vertebrae or otoliths are embedded in plastic, the fluorescent mark keeps at least eight months, although the vertebrae (but not the otoliths) may require some polishing for the marks to regain their former intensity.

These results suggest, overall, that tetracycline marking can be used to test various hypotheses concerning growth of fragile, small pelagic fishes such as investigated there, and to validate age readings based on counts of annual or daily (Pannella 1971) otolith rings, or the analysis of length-frequency data.

Acknowledgements

I wish to express my deep gratitude to all those who helped me in this study, especially to Dr. J. Kesteven, formerly with FAO, for introducing me to physiological investigations on fishes and for enabling me to perform study stages at Duke University, North Carolina, USA and in Scotland, UK; to Dr. W. Nicholson of the US National Fisheries Service who, together with Dr. B. Hettler, helped me disinterestedly with all aspects of my experiments with menhaden in Beaufort, NC, USA. Also my thanks go to Dr. A. Hawkins, the coordinator for my training at the MAFF Laboratory in Scotland, UK, as well as to my former colleagues at IMARPE, R. Mayo, G. Sanchez, A. Alamo and to the technicians I. Navarro, E. Carrasco and C. Jaramillo for their help with marking and maintenance of the fishes in the live boxes and tanks.

Abstract

The growth of anchoveta (*Engraulis ringens*) off Ilo, Peru, was determined using otolith interpretation and length-frequency analysis. The suitability of otolith interpretation for anchoveta growth determination is demonstrated. The use of length-frequency methods, jointly with age data, and the correction of length-frequency for recruitment and gear selectivity are discussed.

Resumen

El crecimiento de la anchoveta peruana frente a Ilo, Perú, fué determinado utilizando la interpretación de los otolitos y los análisis de frecuencia de tallas. La adecuación de los otolitos para determinar el crecimiento de la anchoveta peruana fue probada. El uso conjunto de los análisis de frecuencia de tallas con los datos de edad y la corrección de los sesgos producidos por el reclutamiento y la selección del arte en las frecuencias de tallas son discutidos.

Introduction

The Peruvian anchoveta (*Engraulis ringens*) occurs off the coast of Peru, with heaviest concentrations along the northern and central areas. Anchoveta adult distribution (Villanueva 1975) and their egg distribution (Santander 1987) suggest the presence, during the spawning periods, of isolated groups which may correspond to genetically distinct subpopulations (Mathisen, this vol.). Anchoveta morphological features (Rojas de Mendiola 1971; Tsukayama 1966) and tagging experiments support the hypothesis that the anchoveta resources in the Peruvian southern area (Atico-Ilo) constitute a stock distinct from the northern/central stock documented in Pauly and Tsukayama (1987).

The growth of the northern/central stock has been studied by Pauly and Tsukayama (1983) and especially by Palomares et al. (1987), who also reviewed earlier studies. In contrast with the northern/central stock, little is known on the growth of the southern stock. In this contribution, the growth of the latter stock is determined by means of otolith interpretations and length-frequency analysis based on otoliths and length-frequency data collected in the southern region of Peru in 1979.

Materials and Methods

The length-frequency data used for this analysis were collected monthly during 1979 by IMARPE staff along the southern coastal area comprising the harbors of La Planchada, Atico, Mollendo and Ilo. A subsample of one pair of otoliths for each 0.5 cm total length interval was obtained from the Ilo samples ($n = 163$).

The otoliths were studied with a compound microscope following the standard methods developed for temperate water fishes. The periodicity of ring formation was determined based on the progression, during the course of the year, of the ring in the margin of the otolith and by comparing the number of daily increments in the otoliths with the age determined from the rings. For this last method, a subsample of otoliths ($n = 18$) covering a wide range of ages was prepared for light microscopy, which was performed by applying otolith preparation techniques modified from Brothers (1987).

Age was assigned using the 1st of July as arbitrary birthdate, and an annual age-length key was constructed. The parameters of the von Bertalanffy growth function (VBGF) were estimated by means of the ETAL I program (Gaschütz et al. 1980). As the age-length key does not reflect seasonal changes in growth, the growth curve was fitted without accounting for seasonality.

Fitting of the growth curve to the length-frequency data was done by using the ELEFAN I program (Pauly and David 1981; Pauly 1987; Palomares et al. 1987). Here, the length-frequency data are used to estimate the growth parameters L_{∞} , K, C (amplitude of the seasonal growth oscillations), and WP (time of minimum growth) of the VBGF modified to include seasonal growth oscillation (Pauly and Gaschütz 1979). Also, Modal Progression Analysis or MPA (George and Banerji 1964; Sparre 1987), as included in the Compleat ELEFAN program package of Gayanilo et al. (1988), was used to determine the mean length and associated statistics of each presumed age group in the available length-frequency samples. These means were then interlinked in a fashion thought to reflect growth.

The MPA routine of the Compleat ELEFAN uses the method of Bhattacharya (1967) for decomposing length-frequency samples into their component (normal) distribution. For comparison, the method of Cassie (1950), was also applied to the data of Table 2.

The growth increments resulting from MPA were treated as if they were tagging/recapture data, using each of the successive mean lengths as if they were tagging (length at age t) and recapture lengths (length at age $t + \Delta t$). The age-at-length data obtained by reading the available otoliths were also used to derive growth increments (i.e., "tagging/recapture" data). This was achieved: (i) by using only the increments between year groups and counting twice the increment between age 1 and 2, which is well represented in the samples (see Table 2) and (ii) by using the appropriate routine of the software documented by Brey et al. (1988). The two sets of growth increment data so obtained were entered, along with that obtained from MPA, into the appropriate routine of the Compleat ELEFAN package, and the latter used - along the lines suggested by Morgan (1987) - to estimate growth parameters by simultaneous analysis of length-frequency and growth increment data (Gayanilo et al. 1988).

To correct for the bias introduced by incomplete recruitment and gear selection, the original length-frequency data were corrected using the methods described in Pauly (1986, 1987). As the probabilities of capture in the southern stock can be assumed to be similar to those in the northern/central stock, the probabilities of capture of Palomares et al. (1987), pertaining to the northern/central stock, were used for the correction. All length-based analyses were then repeated using the corrected length-frequencies.

Results

Otolith Interpretation

Anchoveta otoliths are small elongated bodies with a sharp rostrum and well-developed antirostrum. When observed with a compound microscope and reflected light against a dark background, a concentric pattern of bright (opaque) and dark (translucent or hyaline) rings appeared. The definition of the rings improved when the otoliths were immersed in a dense medium (glycerin). The presence of faint false rings obscured in some cases the otolith interpretation.

Otolith interpretation is a dual process consisting of (1) growth ring identification and interpretation and (2) determination of ring periodicity and validation of results.

To assess the objectivity of the interpretation, the otoliths were read three times; a level of 94% coincidence was obtained which showed consistency in the interpretation. Moreover, in a comparative reading exercise between an expert sardine otolith reader without experience in anchoveta otolith interpretation (Ms. G. Cárdenas, IMARPE) and the author, an agreement of 86% was achieved. Thus, anchoveta otolith interpretation was considered reliable.

The determination of the periodicity of the ring formation was made difficult by the thinness and transparency of the otolith margin. Some error might have occurred in the identification of the ring formed in the edge, principally when the opaque ring was in its initial development. Nevertheless, when plotting the monthly percentage of hyaline rings in the otolith edge along the year, the formation of one hyaline ring per year was evident (Fig. 1).

Under the light microscope, the otoliths showed a recurrent pattern of light and dark rings (Pannella 1971) laid down with daily periodicity (Rojas de Mendiola and Gómez 1981). The increments were enumerated along the posterior otolith radius and the number of increments versus the number of hyaline rings in each otolith were plotted (Fig. 2.). The correlation between both variables was not very high ($r = 0.81$). This might be due to the bias introduced by the long spawning period of anchoveta (up to 6 months) and to the failure of the light microscope in detecting the thin increments (0.5 - 0.7 μm) laid down in the hyaline rings of fish older than one year (Morales-Nin 1988). Nevertheless, the age in days and in years for age 1 was close enough to validate the periodicity of the first annulus. Therefore, the two validation methods used here provided sufficient evidence of the annual formation of the rings and it can be concluded, therefore, the age determinations by means of annuli are essentially correct.

Table 1 presents the validated age-length key derived here.

Length-Frequency Analysis

The length-frequency distribution showed notable monthly difference in structure (Table 2).

The analysis of these data using Cassie's (1950) probability paper method and modal progression analysis (MPA) usually suggested the presence of four age groups. However, a fifth group appeared in June (Fig. 3.). The mean lengths obtained for ages 0, 1 and 2 were similar to the means from otolith reading. The mean length of age 3 was different, probably due to overlapping in the length-frequencies caused by the low growth rate of old fishes (Table 3). MPA showed the presence of young fishes following the months of maximum spawning and clear seasonal growth oscillations in the age groups 1 and 2 (Fig. 3).

When the length-frequency data were corrected for recruitment and gear selection, the growth parameters obtained using ELEFAN I showed a clear change and a better fit (Fig. 4B) than without such correction (Fig. 4A, Table 6). The main change was the increase of K, which was higher (Pauly 1986) and hence, closer to the values obtained from otolith readings.

The mean lengths obtained of various age groups estimated by the Bhattacharya method (Fig. 3) and converted into growth increments using MPA are given in Table 4, along with the two sets of growth increments derived from otoliths.

The three sets of growth increment data were analyzed jointly with the length-frequency to improve the fit of the growth parameters. Two independent calculations were done for each set of growth increments, one using the uncorrected length-frequency data, and the other relying on the length-frequency data corrected for incomplete recruitment and gear selection (see Table 5). Table 6 presents the results.

^dSee also Table 5.

Discussion

The mean length-at-age obtained from the otolith reading and the length-based methods were similar (Table 3). Cassie's method produced the more divergent means, probably due to the subjectivity of the selection of the inflection points, which were not very clear. The Bhattacharya method, as incorporated in the MPA routine of the Compleat ELEFAN package, provided better results.

The growth parameters determined by otolith reading and by the different programs for length-frequency analysis (ELEFAN I and ELEFAN V plus growth increment files) were rather variable. However, clear trends emerged, notably with regard to the effect of correcting the length-frequency data for incomplete recruitment and/or selection: K was consistently higher when the length-frequency data were corrected. The growth performance index $\phi' = \log_{10}K + 2\log_{10}L_{\infty}$ (Pauly and Munro 1984; Moreau et al. 1986) for corrected L/F data was very close to the values reported for the northern/central stock of Peruvian anchoveta (Palomares et al. 1987, Fig. 15). Indeed, the mean of the 5 usable values in Table 6 is $\phi' = 2.665$, precisely the value estimated for the late 1970s by Palomares et al. (1987, Fig. 5B).

The ELEFAN I results were in the range of values reported for the northern/central stock, but lower than the growth parameters for this stock in 1979. However, the growth parameters obtained from the corrected length-frequency were closer to the values reported for the northern/central stock (see Table 6 and Palomares et al. 1987).

The results of the combined use of length-frequency analysis and growth increments suggested that the annual growth increments derived from otolith data (sets 2 and 3 in Table 4) gave a better fit than the increments obtained from MPA (set 1 in Table 4). The growth increments from otolith data weighted by abundance (set 2 in Table 4) gave a better fit than the more numerous, but shorter and more variable growth increments in set 3, where more weight is given to the interval between ages 0 and 1 than in the other two sets. This greater weight of the growth of the youngest fishes might be responsible for the higher K that was obtained. Nevertheless, when the corrected length-frequency data were used, this effect was compensated for (see Table 5).

The correction for recruitment and gear selection of the length-frequency data strongly affected the K growth parameter estimation. The estimates of K obtained after the correction were much closer to the value obtained from otolith reading than without the correction (Table 6). In some simulations, the ELEFAN I program was found to overestimate L_{∞} and underestimate K (Rosenberg and Beddington 1987; Hampton and Majkowski 1987). This effect appears to be overcome in the case of the Peruvian anchoveta after the length-frequency data were corrected for incomplete recruitment and gear selection. The estimates of the seasonal growth parameters (C and WP) also improved when the length-frequencies were corrected and reached values closer to those of the northern/central stock (Palomares et al. 1987) and which also were in concordance with the environmental fluctuations (Bakun 1987).

This is the first growth study of the southern Peruvian anchoveta stock and one of the first applications of a method for simultaneous analysis of length and age data derived from Morgan (1987). It may be premature to propose which of the growth parameter sets in Table 6 are the most accurate. Nevertheless, the suitability of otoliths for Peruvian anchoveta age determination has been demonstrated. Here, the match of our otolith-based parameter estimates with those of Aguayo (1979) from northern Chile is particularly notable, given that anchoveta from southern Peru and northern Chile are presumed to belong to the same stock. Also, a marked improvement of the growth estimates following the correction of length-frequency data for incomplete recruitment and gear selection bias was made evident. However, it may be necessary to continue studies of this type, including otolith data from more landing areas, to have a reliable estimates of anchoveta growth parameters. Also, it would be advisable to jointly study the growth of the Chilean and southern Peruvian components of the southern anchoveta stock.

Acknowledgements

The author wishes to thank Dr. Rogelio Villanueva, Executive Director of IMARPE, for kindly providing the otolith and length-frequency data used in this study. Thanks are also due to his staff in the Pelagic Resources Division, especially Ms. Gladys Cárdenas and Ms. Nora Peña, for their cooperation and help. Mr. F. "Nonong" C. Gayanilo, Jr. and Ms. Mina Soriano are thanked for their help with the ETAL I and ELEFAN programs and also for allowing the use of their version of the Compleat ELEFAN program before it was ready for distribution. Dr. D. Pauly is specially thanked for his discussions, and for his suggestion to include this work in the present volume.

The research carried out as reported upon here was part of the project "Tropical Fish Age Determination by Means of Otolith Microstructure and Length-Frequency Analysis," FAO André Mayer Fellowship Biennium 1987-1988, which is here gratefully acknowledged.

Abstract

A length-structured version of Virtual Population Analysis, implemented through the ELEFAN III computer program, was used to estimate, on a monthly basis, anchoveta (*Engraulis ringens*) biomass, recruitment, as well as fishing and natural mortalities off Peru for the period 1953 to 1985. This analysis, pertaining to the northern/central stock of anchoveta, took into account the predation effects of mackerel, horse mackerel, hake, bonito, guano birds (three species) and pinnipeds (two species), and was calibrated using acoustic estimates of anchoveta biomass.

The resulting time series demonstrate the impact of El Niño events on anchoveta population dynamics, and allow separation of the effects of various anchoveta predators from that of the fishery.

Resumen

Se estimaron, en una base mensual, la biomasa, reclutamiento y la mortalidad natural y por pesca de la anchoveta peruana para el período 1953 a 1985, mediante el análisis de Población Virtual con estructuras por longitudes implementado en el programa ELEFAN III. Este análisis, llevado a cabo para el stock norte/central, consideró los efectos de predación de la caballa, jurel, merluza, bonito, aves guaneras (3 especies) y pinnípedos (2 especies) y fué calibrado usando estimaciones de biomasa obtenidas por medio de evaluaciones acústicas.

La serie de tiempo resultante demuestran el impacto de los eventos El Niño sobre la dinámica de la población de anchoveta y permite visualizar por separado el efecto de los predadores y de la pesquería.

Introduction

This contribution presents time series of anchoveta (*Engraulis ringens*) biomass recruitment and mortality on a time scale (one month) that is sufficiently small for capturing the rapid changes that characterize this resource. Monthly time series of various aspects of the population dynamics of anchoveta have been presented earlier (Palomares et al. 1987; Pauly et al. 1987a). This contribution aims to:

- i) extend (to 1985) the previous time series, which covered the years 1953 to 1982;
- ii) include in the analysis the predatory effects of horse mackerel (*Trachurus murphyi*), mackerel (*Scomber japonicus*) and hake (*Merluccius gayi*), which were not explicitly considered earlier; and thus,

*ICLARM Contribution No. 512.

- iii) reduce the uncertainty associated with the input values of baseline natural mortality (M_0), an important parameter of Virtual Population Analysis (VPA), when this is implemented such as to explicitly account for predation.

This contribution represents, as far as the estimation of anchoveta biomass (and related statistics) is concerned, the "third iteration" mentioned by Pauly and Tsukayama (1987). As was also the case with the previous iterations, the biomass estimates presented here do not question the validity of the available independent estimate of anchoveta biomass off Peru obtained through acoustics and other methods. Rather, these were used to calibrate our VPA's, i.e., to estimate values of baseline natural mortality (M_0) which made the VPA results compatible with the independent biomass estimates.

Materials

The data used for this analysis largely overlap with those used in Pauly et al. (1987a). However, more information was available at the time this analysis was performed. Among other things, we used Tables 1 to 5, covering the period 1983 to 1987, in addition to the catch and catch composition data from Tables 1 to 30 of Tsukayama and Palomares (1987), covering the period 1953 to 1982. As in the previous analysis, all monthly nominal catches were multiplied with a factor of 1.2 to account for unrecorded catches (Castillo and Mendo 1987).

Total monthly withdrawals from the anchoveta population were computed as the sum of anchoveta consumption by the predators explicitly accounted for, plus the catch taken by the fishery (Table 6). In addition to the predator groups considered in Pauly et al. (1987a), i.e., cormorants, boobies and pelicans (from Muck and Pauly 1987); bonito (from Pauly et al. 1987b); sea lions and fur seals (from Muck and Fuentes 1987), the anchoveta consumption estimates of mackerel and horse mackerel (from Muck and Sanchez 1987), and hake (from Muck et al., this

Table 1. Monthly catch (in $t \times 10^3$), per cent catch composition and condition factor (c.f.) of Peruvian anchoveta (*E. ringens*, northern/central stock, 4-14°S) based on data collected by IMARPE staff in 1983.

Tabla 1. Capturas mensuales (en $t \times 1,000$), composición en porcentaje y factor de condición (c.f.) de la anchoveta peruana (*E. ringens*, stock norte/central, 4-14°S) basado en datos colectados por personal de IMARPE en 1983.

vol.) were also included. These contributions contain anchoveta length-frequency data from stomach contents showing that the predators in question consume anchoveta of roughly the same size composition as is taken by the fishery, thus allowing pooling of catch and consumption data. Tables 1 to 5 (and Tables 1 to 30 of Tsukayama and Palomares 1987) were raised to total withdrawals as follows:

$$RF_{(i)} = \text{withdrawals}/W_{s(i)} \quad ...1)$$

where RF is the raising factor for each month (i) and $W_{s(i)}$ is the weight of the % catch composition data in month (i). The values of $W_{s(i)}$ were computed as

$$W_{s(i)} = \sum_{j=1}^n f_{ij} W_{ij} \quad ...2)$$

where W_{ij} is the mean weight of fish in class j of sample i, n the total number of length classes in that sample, and f_{ij} the % frequency of class j in sample i. The mean weight of the fish in each length class interval was obtained via length-weight relationships of the form:

$$W = a_i L^b \quad ...3)$$

from

$$W = 1/(L_{j2}-L_{j1}) a_j/(b+1) [L_{j2}b+1 - L_{j1}b+1] \quad ...4)$$

where L_{j1} and L_{j2} are the lower and upper limits of class (j), and which provides an unbiased estimate of the mean weight of fish in a given length class (Beyer 1987). The value of b used in equation (4) was set equal to 3 and the appropriate values of a = c.f./100 (see Tables 1-5 for c.f. values for 1983-1987. Equations (1) to (4) were applied 403 times, for every month from January 1953 to July 1987, i.e., to the data in Tables 1 to 30 of Tsukayama and Palomares (1987), to the data in Tables 1 to 5, and to the samples interpolated to fill in gaps.

Missing % length-composition data were linearly interpolated between adjacent months for all years with data gaps except for 1953 and 1983 for which data for the corresponding months of 1955 and 1984, respectively, were inserted. In a few cases, minimum catch estimates, set at 1 tonne, were inserted in the catch-at-length matrix to prevent underflow and/or division by zero errors. We expect these manipulations to have little impact on final results - at least when compared with the large impact of the parameter M_0 , of which only approximate values could be obtained (see below).

Methods (adapted from Pauly et al. 1987a)

Brief Description of Length-Structured VPA

Beverton and Holt (1957) showed that the catch (C_i) from a population during a unit time period (i) is equal to the product of the population size at the beginning of the time period (N_i) times the fraction of the deaths caused by fishing, times the fraction of total deaths, or:

$$C_i = \frac{F_i}{Z_i} (1 - e^{-Z_i}) N_i \quad ...5)$$

where F_i is the fishing mortality in the ith period, M is the natural mortality, generally assumed constant for all period, and $Z_i = F_i + M$.

The version of Beverton and Holt's catch equation which has become most widely used for stock assessment purposes, however, is:

$$\frac{N_{i+1}}{C_i} = \frac{Z_i \cdot e^{-Z_i}}{F_i (1 - e^{-Z_i})} \quad ...6)$$

also written

$$\frac{C_i}{N_{i+1}} = \frac{F_i}{Z_i} (e^{-Z_i} - 1) \quad ...7)$$

which is the equation in Gulland's (1965) VPA and which can be derived from equation (5) by substituting for N_i the relationship:

$$N_i = N_{i+1} e^{Z_i} \quad ...8)$$

Given values of C_i and an estimate of M (here: " M_0 "), equation (7) can be used to estimate (retroactively) the size of past cohorts (i.e., of groups of fish born at the same time and exposed to the same mortalities throughout their lives), given an estimate of N_{i+1} from which to start the computation. Such estimate of N_{i+1} (expressing the last population size a cohort had before it went extinct) are usually called "terminal populations" (N_t). Values of N_t can be obtained from:

$$N_t = C_t / F_t \quad ...9)$$

where C_t is the terminal catch (i.e., the last catch taken from a cohort before it went extinct) and F_t is the terminal fishing mortality, i.e., the fishing pressure (here inclusive of predation) that generated C_t (Mesnil 1980; Pauly 1984).

The feature of VPA that is most important in the context of this contribution is that, given high withdrawal estimates of population size obtained by repeated application of equations (6) or (7) tend to rapidly converge toward their true value, and hence, usually provide, given reasonable estimates of M , very reliable estimates of recruitment (Pope 1972; Pauly 1984). Moreover, the speed of convergence from the guessed values of N_t (i.e., values of N_t based on guessed values of F_t) toward accurate values of N_t is a function of the ratio of F to M . That is, the higher the proportion of the cohort is which ends up being withdrawn by the fishery and eaten by horse mackerel, mackerel, hake, bonito, birds and seals, the more reliable the population estimates will be. This is the reason why we have accounted explicitly here for the anchoveta consumed by these predators, and thus left M_0 low, rather than replace predation by a higher, constant estimate of M .

Three forms of VPA, all included in the ELEFAN III program, may be distinguished (Pauly and Tsukayama 1983; Gayanilo et al. 1988):

- i) VPA I, which is the version originally proposed by Gulland (1965) and which Pope (1972) reformulated as "Cohort Analysis";
- ii) VPA II, the VPA equivalent of Jones' (1981) "Length Cohort Analysis" (see also Jones and van Zalinge 1981; Pauly 1984; Pauly and Morgan 1987); and
- iii) VPA III, which combines features of (i) and (ii) and which is documented in Pauly and Tsukayama (1983), in Pope et al. (p. 386-390) in Morgan and Pauly (1987) and in Gayanilo et al. (1988).

VPA III is a version of VPA I performed on "cohorts" obtained by superimposing growth curves, drawn at monthly intervals, onto a set of catch-at-length data, the catch pertaining to each "cohort" and month being simply that part of the monthly catches contained between two adjacent growth curves (see Fig. 1).

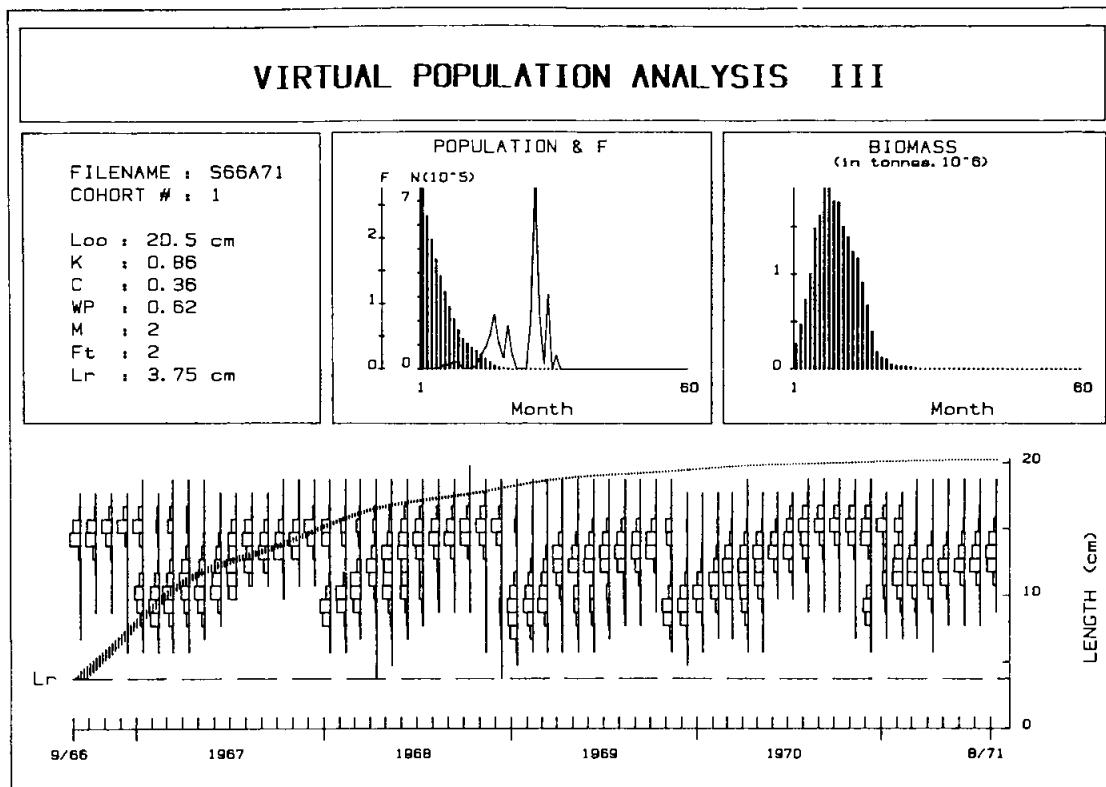

Fig. 1. Facsimile of an ELEFAN III output (via plotter) showing monthly catch-at-length data (not to scale) and one of the many monthly cohorts which can be superimposed on these data. The upper two panels show the population and fishing mortality estimate pertaining to this cohort, along with its biomass (rightmost panel). The population estimate pertaining to month 1 is an expression of recruitment of anchoveta of length $L_r = 3.75-4.75$ cm (from Pauly et al. 1987a).

Fig. 1. Ejemplo de los resultados obtenidos con el ELEFAN III (via plotter) que muestra datos mensuales de la composición de la captura por longitudes (sin escala) y uno de los tantos cohortes que pueden ser sobreponibles en esos datos. Los dos paneles de arriba muestran las estimaciones de la población y la mortalidad por pesca de esta cohorte junto a su biomasa (panel de la derecha). La población estimada correspondiente al mes 1 es una expresión del reclutamiento de la anchoveta de longitud $L_r = 3.75-4.75$ cm (de Pauly et al. 1987a).

For such cohorts to really consist of fish recruited at the same time, the growth curves used for "slicing up" a cohort must be obviously as close to the true growth curve of that cohort as possible. This, among other things, makes it imperative that a seasonally oscillating growth curve be used, since, as shown in Pauly and Ingles (1981), Pauly (1982) and Longhurst and Pauly (1987), virtually all natural fish stocks, including those occurring in tropical waters, display seasonally oscillating growth (see also Palomares et al. 1987).

In reality, not all fish of a given cohort have the same growth parameters, however, and it can be expected that some fish will "leave their cohort" because they grow either faster or slower than predicted by the mean cohort growth curve. Such differences in growth rate should here have the effect of artificially increasing the autocorrelation between estimates of recruitment (see Mendelsohn and Mendo 1987).

The growth curves used here to "slice cohorts" were based on the seasonally oscillating version of the von Bertalanffy Growth Function (VBGF) developed by Pauly and Gaschütz (1979), i.e.,

$$L_t = L_{\infty}(1 - \exp(-[K(t-t_0)])) = [KC/2\pi \sin 2\pi(t-t_s)] \quad \dots 10)$$

where L_t is the length at age t , L_{∞} the asymptotic length, K a growth constant, t_0 the "age" at which length is zero if the fish always grew according to the equation, C is a dimensionless constant expressing the amplitude of the growth oscillations and t_s is the time (with respect to $t = 0$) at the beginning of a sinusoidal growth oscillation of a one-year period.

For practical purposes, the estimation of t_s was replaced by the estimation of a Winter Point (WP), defined as:

$$t_s + 0.5 = WP \quad ...11)$$

which expresses (as a fraction of the year) the time during which growth is slowest. It should be mentioned here that the ELEFAN programs, being based on length-frequency data (rather than length-at-age data) do not allow for the estimation, nor require estimates of t_0 , hence of *absolute* ages; all "ages" used internally by the programs are *relative* ages, expressed in relation to an arbitrary birthdate that is set internally and not output by the program.

For this reason, our estimates of growth parameters, biomass, recruitment, etc. are not affected by Somers' (1988) observation that equation (10) produces slightly biased estimates of t_0 (when applied to age-at-length data).

The VPA III routines of ELEFAN III were applied to the available catch-at-length data, using for 1953 to 1982 the growth parameters in Table 3 of Palomares et al. (1987), new growth parameter estimates based on Tables 1 to 5 and on the ELEFAN I program (Pauly and David 1981; Gayanilo et al. 1988) for the years 1983 to 1987. The year-to-year differences in the values of these growth parameters caused a slight overlap of some "cohorts" (i.e., some of the catch data were used twice), and small gaps (i.e., some of the catch data were not included in any cohort). This source of error could have been avoided by using the same growth parameters throughout. This, however, would have caused a large bias, given the strong positive trend in anchoveta growth performance documented in Palomares et al. (1987).

Estimation of Monthly Recruitment and Biomass

Monthly population estimates per length class were obtained by regrouping monthly values of N_i obtained on a cohort basis into regular class intervals (the same intervals as those in which the catch data were originally grouped). The population estimates (in numbers) of the smallest class considered here (3.75 to 4.75 cm) are here defined as "recruitment" (of fish with mean length 4.25 cm).

The population estimates (in numbers), by length class, were then multiplied, for each month and length class separately by the appropriate mean weight values (see equation 4) to obtain monthly population biomass by length class (Fig. 2).

The analyses for 1953 to 1982 were run with " F_t " = 5 year⁻¹, while those for 1983-1987 were run with " F_t " = 2 year⁻¹, because predation was not included as part of fishing "mortality" for the latter period. It is recalled that these values (a) pertain to $Z \cdot M_p$ (i.e., to the sum of true fishing mortality plus all sources of natural mortality represented by distinct predators and (b) that values of F_t have little impact on final results, especially on recruitment estimates.

Estimation of Natural and Fishing Mortalities

The natural mortality (M_p) exerted by any given predator (p) with anchoveta consumption $C_{P(i)}$ was estimated, for each month (i) from

$$M_{P(i)} = \text{anchoveta consumption } (C_{P(i)}) / \text{anchoveta biomass } (i) \quad ...12)$$

Similarly, fishing mortality (F) was estimated from

$$F_i = \text{anchoveta fishery catch } (i) / \text{anchoveta biomass } (i) \quad ...13)$$

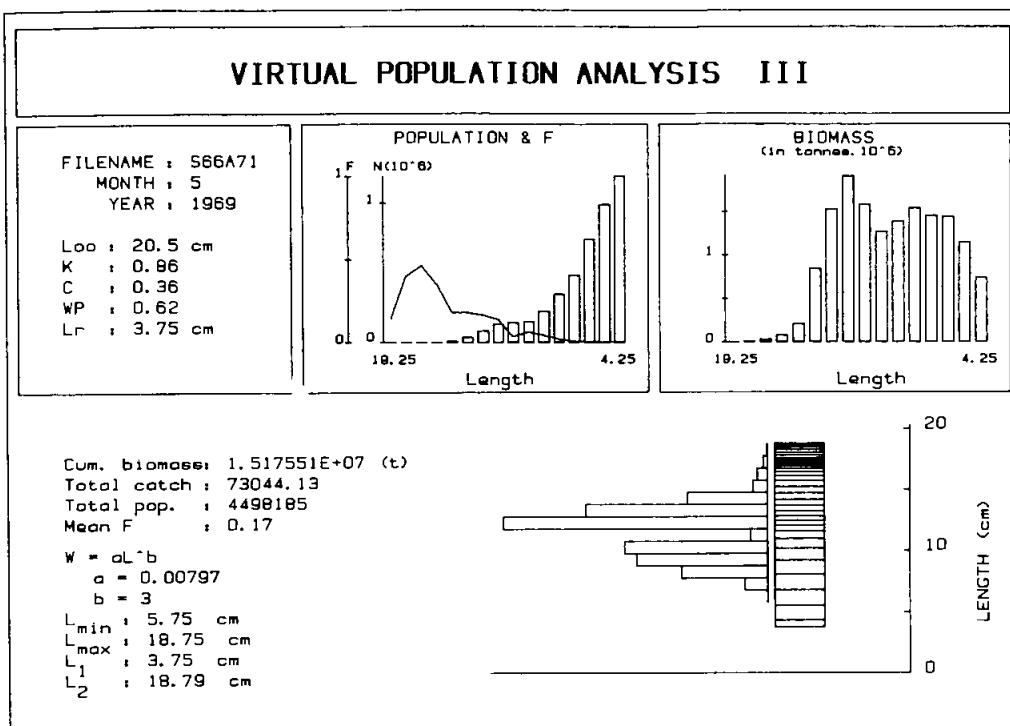

Fig. 2. Facsimile of an ELEFAN III output (via plotter) showing summary of result of a VPA III pertaining to a given month (here May 1969), and showing the catch data (lower panel, right, histograms) the cohorts "passing through" that month (box with narrowing lines), the size structure of the population (upper boxes, center and right), as well as summary statistics (lower panel, left) (from Pauly et al. 1987a).

Fig. 2. Ejemplo de los resultados obtenidos con el ELEFAN III (via plotter) mostrando un resumen de los resultados del VPA III correspondientes a un mes dado (aquí Mayo 1969), y los datos de captura (panel inferior de la derecha, histogramas) del cohorte que está "pasando a través" de ese mes (cuadro con líneas que se juntan), la estructura por tamaños de la población (cuadros de arriba, centro y derecho), así como un resumen estadístico (panel de abajo, izquierdo) (de Pauly et al. 1987a).

Thus, all estimates of mortality presented here pertain to weights, not numbers. From these data, total mortality (Z) can be estimated from:

$$Z_i = F_i + M_o + \sum_{m=1}^5 p_i \quad \dots 14)$$

where m is the number of predator groups considered here, i.e., horse mackerel and mackerel, hake, bonito, birds and seals.

Results and Discussion

Estimate of Growth Parameters for the Years 1983 to 1987

The length-frequency data in Tables 1 to 5 had too many gaps to allow estimation of growth parameters for different cohorts or years. Therefore, we applied the ELEFAN I program to all data in Tables 1 to 5. This resulted in the following estimates: asymptotic length $L_\infty = 20.3$ cm (TL); growth constant $K = 0.8$ year $^{-1}$; amplitude of seasonal growth oscillation $C = 0.27$ and Winter Point (i.e., time of the year with lowest growth rate) $WP = 0.62$.

These values resemble those estimated by Palomares et al (1987). However, the growth performance index $\phi' = \log_{10} K + 2\log_{10} L_\infty$ (Pauly 1979; Pauly and Munro 1984) for this period was 2.518, i.e., lower than estimated for the late 1970s and early 1980s. The new estimate of ϕ' is still higher, however, than the values estimated for the 1950s, thus confirming, overall, the trend expressed by Fig. 3.

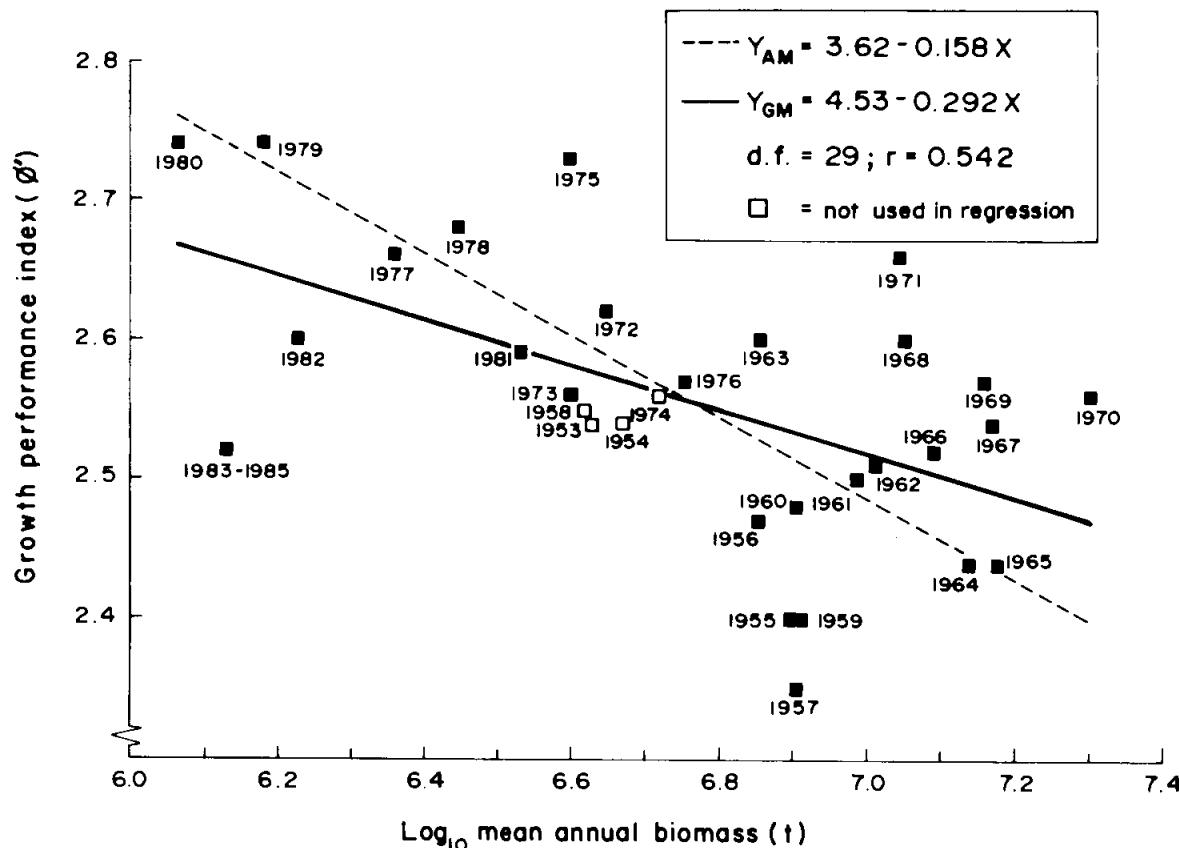

Fig. 3. Relationship between the growth performance index of anchoveta ($\phi' = \log_{10} K + 2\log_{10} L_\infty$; K in year $^{-1}$; L_∞ in cm T.L.) and mean anchoveta biomass off Peru (4-14°S), 1953 to 1985 (this contribution). The ϕ' values are from Palomares et al. (1987) and the present contribution. Note clear evidence of density-dependent growth of anchoveta.

Fig. 3. Relación entre el índice de eficacia en crecimiento de la anchoveta ($\phi' = \log_{10} K + 2 \log_{10} L_\infty$; K año $^{-1}$; L_∞ en cm L.T.) y la biomasa promedio de anchoveta (4-14°S) 1953 a 1985 (esta contribución). Los valores de ϕ' son de Palomares et al. (1987) y de la presente contribución. Nótese la clara evidencia de la densodependencia del crecimiento de la anchoveta.

Estimates of M_o and Their Implication

Table 7 and Fig. 4 document the values of M_o obtained iteratively, i.e., by changing the input value of M_o for a given month until the biomass estimated by VPA matched the independent biomass estimates in Table 7.

As might be seen, the estimated values of M_o are extremely variable. Thus, our extrapolation of $M_o = 0.6$ year $^{-1}$ for the period 1953 to 1963 is tentative. On the other hand, the overall level of M_o is lower, by a factor of about three, than the level of M_o in Pauly et al. (1987a). This is due to the explicit consideration of the predation effect of horse mackerel, mackerel and hake, whose anchoveta consumption is now included in the total withdrawals (Table 6).

Indeed, if one assumes that the independent biomass estimates are accurate, then the drop to zero of the M_o values in the early 1970s suggests that total withdrawals were overestimated for that period.

A similar decline was demonstrated by Pauly et al. (1987a) for the early 1970s, and shown to parallel independent (tagging) estimates of natural mortality. The explicit consideration here

the effect of new predators - especially horse mackerel - has now further reduced our M_0 estimates. Our VPA biomass estimates are, for the early 1970s, lower than the independent estimate (see Fig. 4) suggesting that, for that period, M_0 should have been negative, or more reasonably, that the withdrawals and the observed biomasses are mutually incompatible. One way to correct for this would be to identify (in a fourth iteration) a mechanism leading to reduced estimates of consumption by the various anchoveta predators during the period in question.

Table 7. Independent estimates of anchoveta biomass off Peru (4-14°S) and estimated values of baseline natural mortality (M_0) using VPA III (see also Fig. 4).

^aAll values were adjusted through linear inter- and extrapolations to pertain only to the region between 4 and 14°S.

^bSee also Johannesson and Robles (1977).

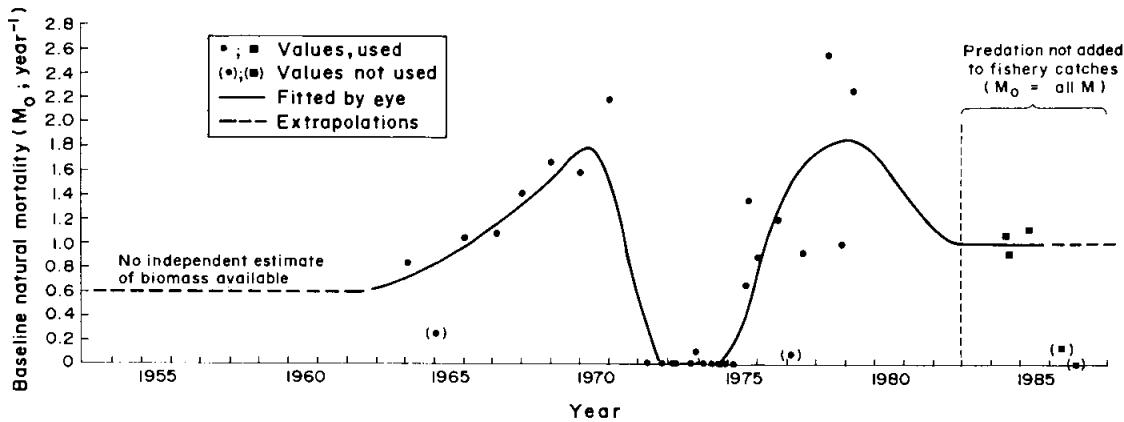

Fig. 4. Estimates of baseline natural mortality (M_0), as required to reproduce independent estimates of anchoveta biomass in Table 7, using the VPA III routine of the ELEFAN III program. Note forward and backward extrapolations, and that high withdrawals, from 1972 to early 1975, precluded reproduction of independent biomass estimates using positive values of M_0 (see text).

Fig. 4. *Estimaciones de la línea base de mortalidad natural (M_0) requeridas para reproducir estimaciones independientes de biomasa de anchoveta en la Tabla 7, usando la rutina del VPA del programa ELEFAN III. Nótese las extrapolaciones hacia adelante y hacia atrás y que las altas remociones, de 1972 y comienzos de 1975, imposibilitan la reproducción de estimaciones independientes de biomasa usando valores positivos de M_0 (ver texto).*

Estimates of Anchoveta Biomass and Recruitment, 1953 to 1985

Table 8 and Fig. 5 present our biomass estimates. Table 8 presents the data on a monthly basis, while Fig. 5, recalls them as smoothed series, emphasizing the interannual changes.

As might be seen, this time series quite faithfully reflects the known dynamics of the stock, inclusive of rapid decreases associated with El Niño events. This also applies to the early period for which no independent biomass estimates are available (1953 to 1963) and whose overall level of biomass may be higher (or lower, depending on M_0) than indicated. The biomass estimates for the early 1970s are, as discussed above, slightly too high. This improves, however, in the late 1970s and early 1980s, and indeed the near total collapse following the strong 1982-1983 El Niño event is rather well reproduced.

We have abstained from presenting in table form the length composition of the biomass estimates summarized in Table 8 and Fig. 5, but these are available on 5-1/4" MSDOS diskettes, along with our inputs and other data (see Appendix I).

Fig. 6 presents our estimates of anchoveta recruitment^a for the period 1953 to 1985. As might be seen, these time series resemble those of biomass, which is not surprising for a resource in which 0.5 to 1.5 year old fish constitute the bulk of the biomass.

Two important features of this time series match those reported earlier by Pauly et al. (1987a), i.e.,

- i) the increased within-year variability of recruitment from the late 1950s to the late 1960s, probably an effect of the increasing fishing pressure; and
- ii) the fact that the recruitment collapse of 1971 appears to have occurred *before* the onset of the 1972-1973 El Niño event, as also observed by Mendelsohn and Mendo (1987).

Item (ii) implies that the El Niño event of 1972-1973 (at least as conventionally defined, i.e., as temperature anomaly) cannot have been the cause for the collapse of the fishery.

Natural and Fishing Mortality of Anchoveta, 1953 to 1985

Fig. 7 presents our estimates of predator-specific M values, our estimates of total M , of F and of $Z = M + F$. As might be seen, horse mackerel is by far the most important predator of anchoveta, followed (in the 1950s at least) by cormorants, bonito, mackerel and hake.

^aEditors' note: These estimates are also documented in Table 2 of Appendix I.

Table 8. VPA III estimates of anchoveta biomass off Peru (4°-14°S), January 1953 to August 1985 (in tonnes).
 Tabla 8. Estimaciones de biomasa de anchoveta frente al Perú (4°-14°S) mediante el VPA III, Enero 1953 a Agosto 1985 (en toneladas).

| Year | Jan | Feb | Mar | Apr | May | Jun | Jul | Aug | Sep | Oct | Nov | Dec |
|------|------------|------------|------------|------------|------------|------------|------------|------------|------------|------------|------------|------------|
| 1953 | 5,273,333 | 5,332,432 | 5,068,336 | 4,752,896 | 4,437,194 | 4,229,566 | 4,032,404 | 3,893,989 | 3,301,880 | 3,343,782 | 3,449,599 | 3,615,833 |

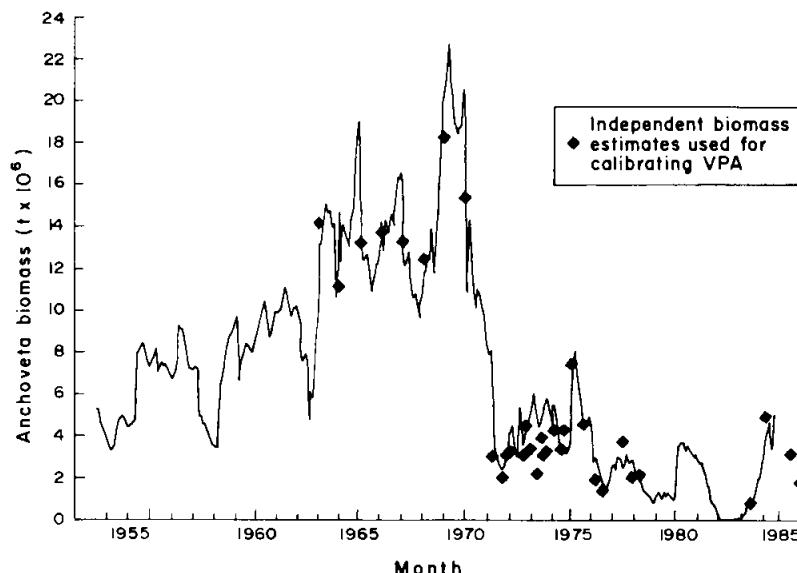

Fig. 5. Biomass estimates of Peruvian anchoveta, 4-14°S, 1953-1985 (obtained through the VPA III routine of the ELEFAN III program, see text) and showing independent biomass estimates used to calibrate VPA.

Fig. 5. Estimaciones de biomasa de la anchoveta peruana 4-14°S, 1953-1985 (obtenida mediante la rutina del VPA III del programa ELEFAN III, ver texto) y estimaciones de biomasa independientes usadas para calibrar el VPA.

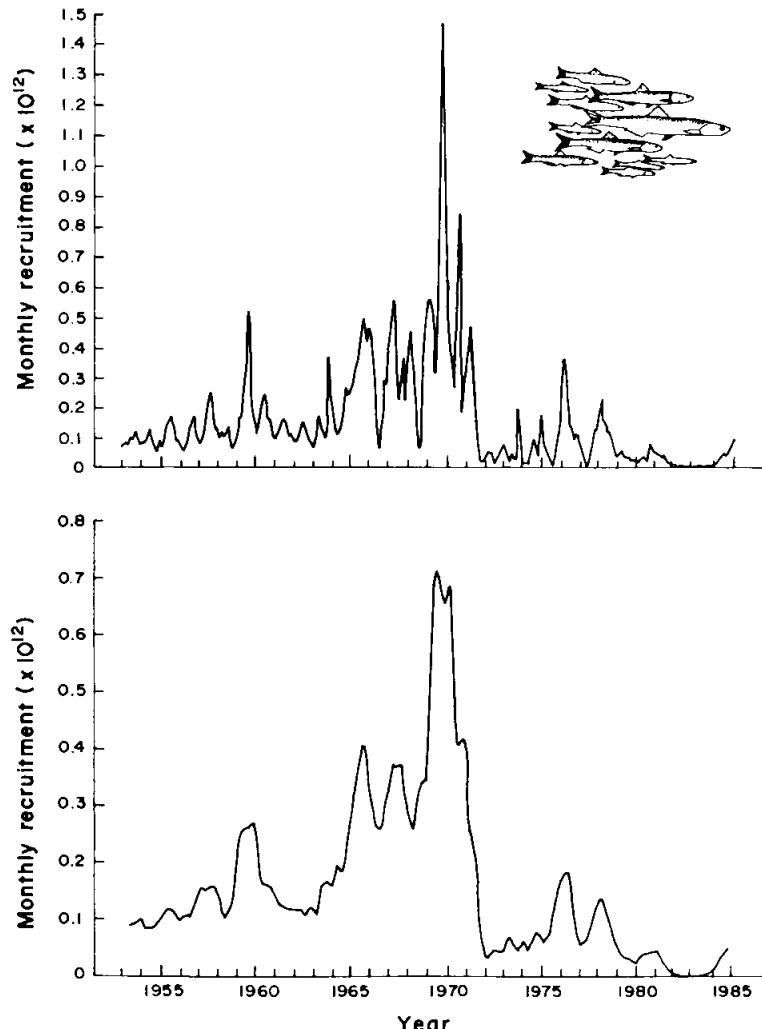

Fig. 6. Time series of recruitment (of fish ranging from 3.75 to 4.75 cm, slightly less than 3 months old) into the anchoveta stock, January 1953 to December 1985. Above: monthly recruitment showing increasing variability, from the late 1950s to 1970, probably due to increasing fishing pressure and leading to recruitment collapse in early 1971, prior to the onset of the 1972-1973 El Niño. Below: smoothed data (using a 12-month running average), showing that the 1960s, which saw the buildup of the fishery, may have been a period of exceptionally and steadily high recruitment.

Fig. 6. Serie temporal de reclutamiento (de peces en un rango de 3.75-4.75 cm, algo menos de tres meses de edad) al stock de anchoveta, Enero 1953 a Diciembre 1985. Arriba: reclutamiento mensual mostrando un incremento en la variabilidad, de fines de la década del 1950 a 1970, probablemente debido al incremento de la presión pesquera y que condujo al colapso del reclutamiento a comienzos de 1971, antes de la aparición del fenómeno de El Niño 1972-1973. Abajo: datos suavizados (usando promedio corrido de 12 meses), mostrando que la década del 1960, que marcó el surgimiento de la pesquería, puede haber sido un período de reclutamiento excepcionalmente alto y constante.

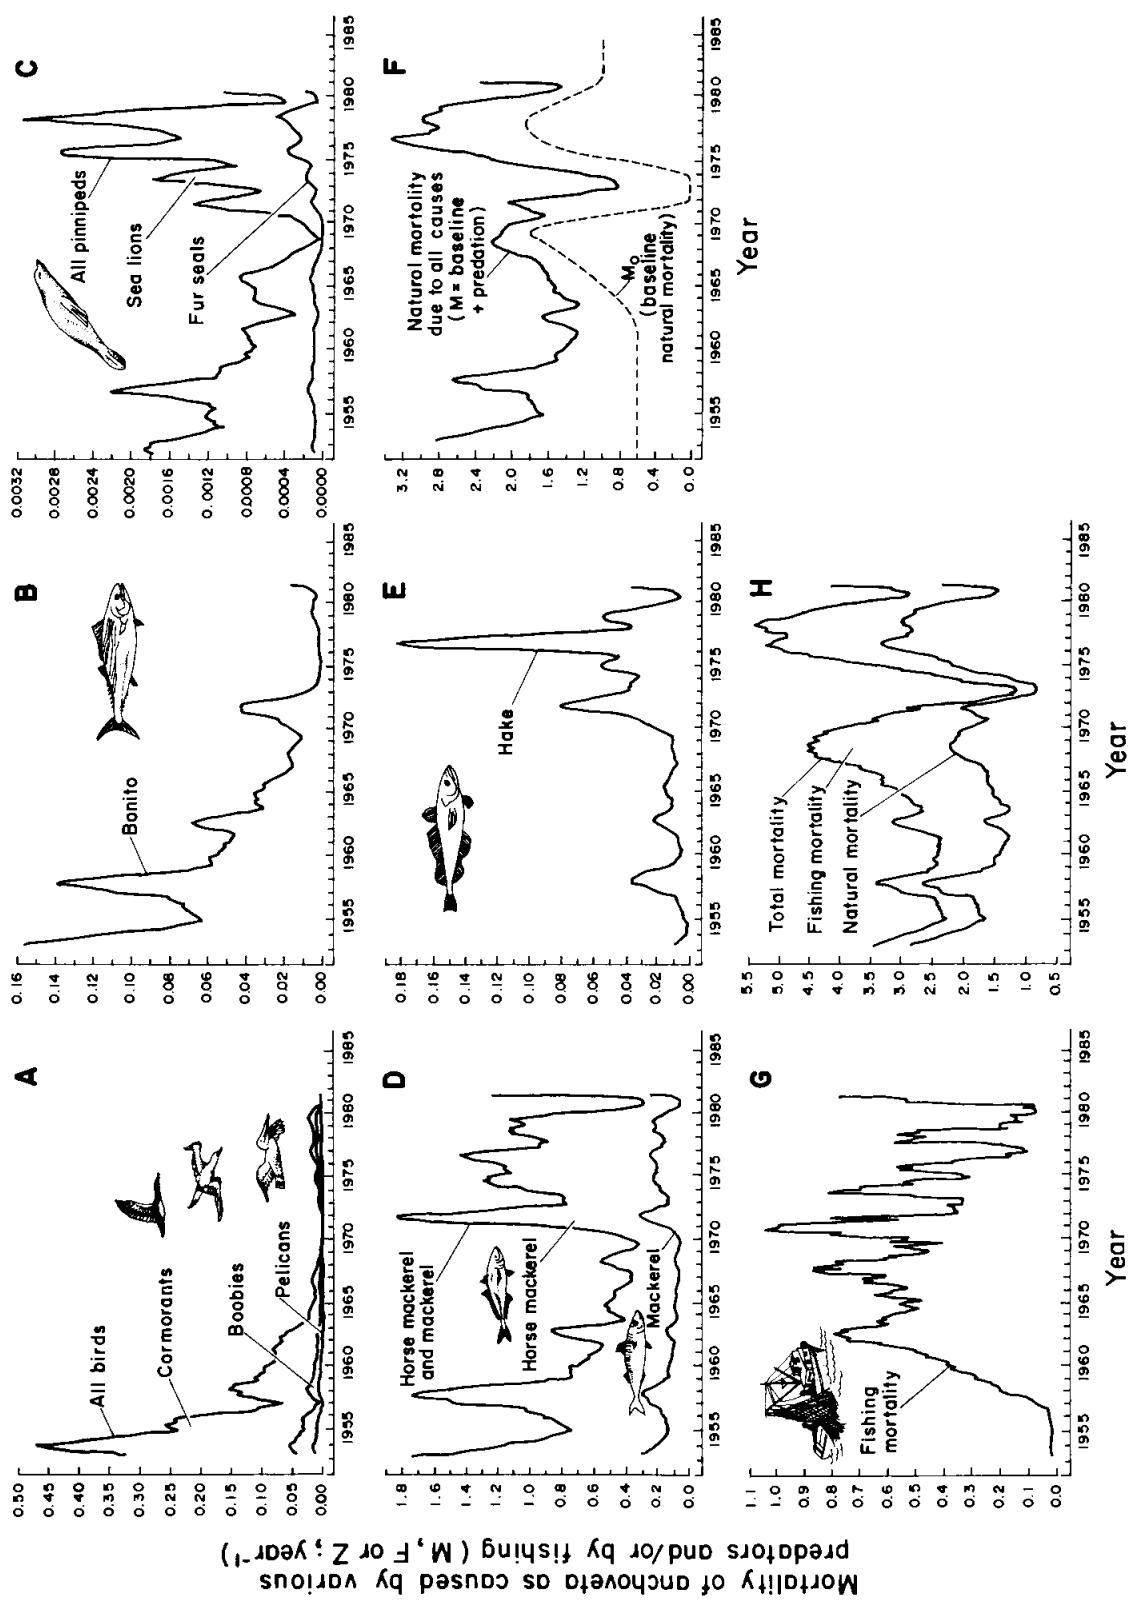

Fig. 7. Estimaciones de mortalidad natural debido a varios predadores (A-E), a todas las causas (F) y estimaciones de mortalidad por pesca (G) y mortalidad total (H) de la anchoveta peruana. Los datos han sido suavizados con promedios corridos de 13 meses para enfatizar las variaciones interanuales. Nótese las escalas diferentes y comparativamente, el gran impacto del jurel.

Fig. 7. Estimates of natural mortality due to various predators (A-E), all causes (F), and estimates of fishing (G) and total mortality (H) of Peruvian anchoveta. Data values smoothed over 13 months to emphasize interannual variations. Note different scales, and comparatively large impact of horse mackerel.

The least important predators were, on the other hand, hake and pinnipeds (at least as far as the stretch of Peruvian coast comprised between 4 and 14°S is concerned). This is not surprising, as the bulk of Peruvian hake and pinnipeds are generally concentrated north and south of 4 - 14°S, respectively.

Overall, natural mortality (baseline + predator-induced) shows no long-term trend, averaging 1.9 year⁻¹ from 1953 to 1985, i.e., about two times the value of the growth parameter K, which was estimated by Palomares et al. (1987) to range from 0.6 to 1.3 year⁻¹, with a mean of 0.9. Thus, M/K is in anchoveta of the order of 2 as is often the case in small fishes (Beverton and Holt 1959; Pauly 1980). The overall consistency of M, and its relationship with K, suggest that our values of M_o are probably not too far off the mark.

Obviously, one could also emphasize the variability of M, which ranged from 0.8 year⁻¹ in the mid 1970s to about 3 year⁻¹ in the late 1970s. We cannot at present explain these changes; they may be real, or they may have to do with erroneous withdrawal estimates (especially with regard to the predation estimates by horse mackerel) or with biases in the acoustic estimate, due e.g. to post-collapse changes in the schooling patterns of anchoveta.

Overall, we feel we have achieved the aims of the third iteration, i.e., to derive new estimates of anchoveta biomass and recruitment while simultaneously accounting for all of its important predators. We leave the refinement of our analyses to a "fourth iteration", which would have to address the problems alluded to above, pertaining to the dip of natural mortality in the early 1970s.

Abstract

Monthly changes in the catchability coefficient in the Peruvian anchoveta (*Engraulis ringens*) fishery are analyzed for the years 1960 through 1982. A clear seasonality in the fluctuation of monthly catchability is found from 1960 through 1971, with higher mean values during the austral summer and lower values in winter. After 1972, catchability increased dramatically and the seasonal pattern changed, becoming higher during mid-spring and fall. It is shown that there is a strong density dependence in these fluctuations. The estimated catchability coefficient (q) was found to be inversely related to population size (B), fitting the power function $q = a \cdot B^b$, with a slope $b = -0.97$. The implications of this compensatory mechanism are discussed and reference is made to some indications of a possible change of state in the Peruvian anchoveta ecosystem, which may have switched the population to a path with a much lower maximum equilibrium level after the fishery collapsed in 1972.

Resumen

Se analizan los cambios mensuales del coeficiente de capturabilidad en la pesquería de la anchoveta peruana (*Engraulis ringens*) en los años 1960 a 1982. Se encuentra una clara estacionalidad en las fluctuaciones de la capturabilidad por meses entre 1960 y 1971, con valores promedios mayores durante el verano austral y valores menores en invierno. Después de 1972 la capturabilidad aumentó dramáticamente y cambió el patrón estacional, haciéndose mayor a mediados de primavera y en otoño. Se muestra que hay una fuerte dependencia de la densidad en estas fluctuaciones. Se encontró que los estimados del coeficiente de capturabilidad (q) están inversamente relacionados con el tamaño de la población (B), ajustándose a la función $q = a \cdot B^b$ con una pendiente $b = -0.97$. Se discuten las implicancias de este mecanismo compensatorio y se hace referencia a algunos indicios de un posible cambio de estado en el ecosistema de la anchoveta peruana, la cual, después del colapso de la pesquería en 1972, habría pasado a un nuevo curso poblacional con un nivel de equilibrio máximo mucho menor.

Introduction

When dealing with the variability and collapse of fish stocks and fisheries, the specialized literature frequently points out the high incidence of collapse amongst small shoaling pelagic fisheries and the features common to these stocks that may explain their high vulnerability to unrestrained fishing (see, for example, Saville 1980; Sharp and Csirke 1983; Beverton et al. 1984; Csirke 1988). One of these features identified to contribute to the higher risk of collapse of these fish stocks and their related fisheries is the density dependence of the catchability coefficient.

Higher catchability with decreasing stock sizes have been reported in several pelagic stocks that have collapsed, such as, for instance, the California sardine (Fox 1974; MacCall 1976), the

Atlantic menhaden (Schaaf 1975, 1980), the Norwegian spring-spawning herring (Ulltang 1976, 1980) and the South African sardine (Shelton and Armstrong 1983). The existence of a similar type of relationship was also suspected on the Peruvian anchoveta that collapsed in the early 1970s, but no clear evidence to this respect was reported until now.

Besides affecting recruitment, the 1972-73 "El Niño" event confined the already reduced anchoveta stock to a much smaller area, which caused an increase in the catchability coefficient that allowed the fleet to obtain higher catch rates even while fishing on a decimated stock (Csirke 1980). Although it occurred at a low abundance level, this did not provide enough evidence of a causal depensatory relationship between catchability coefficient and stock size because at that time the change in catchability was mostly associated with a major environmental factor.

The increased catchability was particularly notorious late in 1971 and early 1972, during the onset of the "El Niño" event. The sequence of events that followed are well known, the fishery collapsed, and fisheries scientists and administrators now tend to agree that the collapse was caused by a combination of both fishery-related and natural factors (i.e., "El Niño"-related adverse environmental conditions, see e.g., Muck, this vol.). Some discussion still goes on, however, on which of these factors are to be blamed the most, to what extent the collapse was avoidable, and if so, what needed to be done and when. Hopefully, knowing more about the behavior of the catchability coefficient may contribute to elucidate some of these questions.

The IMARPE-based international multidisciplinary project that led to the publication of the book edited by Pauly and Tsukayama (1987), provided both the stimulus and the additional sets of data and information needed to analyze the seasonal and year-to-year fluctuations of the catchability coefficient, and to explore further the hypothesis that in the Peruvian anchoveta fishery the catchability coefficient increased as stock size decreased.

Material and Methods

The anchoveta stock referred to here is the one that occurs off northern-central Peru, from the northern end of the species distribution range, at 4°30'S (Jordán 1971), to approximately 14°S. Before collapsing in the early 1970s, the stock in this area accounted for around 80% of the world catches of this species. Tagging, morphometric and other biological studies tend to support the idea that the anchoveta in this area belongs to a same unit stock, and indicated that it has similar and relatively uniform characteristics and mixes little with the anchoveta found further south, off southern Peru and northern Chile.

The analyses in this paper are based on monthly data and estimates from 1960 to 1982, thus covering the most important years in the history of this fishery. Prior to 1960 the fishery was still in an early development phase, total catches represented a fairly small fraction of the total stock and fishing effort data are not readily available for those years. No comparable set of data is at the moment available for the more recent years. Another, much stronger "El Niño" event occurred in 1983-1984, which had a severe impact on the anchoveta stock and called for more drastic regulations and changes in the fishing fleet, gears and fishing operations, all aimed at reducing pressure on the depleted anchoveta stock and improving exploitation of sardines and other small pelagics which had increased in the mean time. This apparently made the collection of reliable anchoveta fishing effort statistics far more difficult besides making it less comparable with previous years.

Total catches by month for 1960-1982 (Table 1) were reported by Tsukayama and Palomares (1987). For the same stock Pauly et al. (1987) estimated the total biomass by size group at the beginning of each month, using a newly developed version of length-structured virtual population analysis (VPA). The mean biomass of the exploited stock for each month (Table 2) was calculated taking the bimonthly average of the VPA biomass estimates of fish larger than or equal to 7.75 cm (mid-length at 8.25 cm in Pauly et al. (1987)).

This stock is only exploited by Peruvian purse seiners, called "bolicheras", and the estimated monthly total fishing effort directed to the anchoveta stock by this fleet is presented in Table 3. The fishing effort estimates are those produced for, and used by, the Panels of Experts on Peruvian Anchoveta until 1973 (IMARPE 1970, 1972, 1973, 1974), which have been updated

Table 1. Nominal catch ($t \cdot 10^3$) of Peruvian anchoveta (*Engraulis ringens*) between 4° and 14° South, by month and by year from 1960 to 1982 (from Tsukiyama and Palomares 1987).

^aValues in parentheses are theoretical estimates of q made on the basis of the available estimates of anchoveta biomass (in Table 2) and equation (3); see text.

following the same procedures for the latter years using IMARPE records. Fishing effort is expressed in GRT-trip (gross registered tonnage per trip) and no adjustments for efficiency were made. Trips usually lasted for 12 to 24 hours and vessels were rarely allowed to make more than one trip per day. The effort data series start in September 1960, when the newly created Marine Resources Research Institute (now the Peruvian Marine Institute - IMARPE) started to collect catch and effort data. No observations are available for some months in 1973, 1977, 1978 and 1982, when catches were obtained through noncommercial operations (e.g., surveys or exploratory fishing), or when commercial operations were mostly directed to other species or were subject to severe regulations and/or restrictions and for which no proper effort records were provided. Total catches in those months were usually small. Fishing mortality per month (Table 4) was calculated by dividing the total catch per month by the estimated mean biomass of the exploited stock.

The catchability coefficient is taken here in the context defined by Paloheimo and Dickie (1964), and monthly values (Table 5) have been estimated by dividing the monthly fishing mortalities by the fishing effort exerted each month on the stock.

The model selected to describe the variation of the catchability coefficient with stock size is that proposed by Fox (1974) and MacCall (1976), which has the form:

$$q = a \cdot B^b \quad \dots 1)$$

where q is the catchability coefficient, B is the mean population size (mean biomass of the exploited stock in this case) and a and b are constants.

In this model the catchability coefficient will increase or decrease depending on the size and absolute value of B , giving rise to a relationship between the catch per unit of effort (C/f) and the stock size (B) of the form

$$C/f = a \cdot B^{b+1} \quad \dots 2)$$

where the usual assumption that catchability remains constant allowing C/f to become a perfect index of abundance is fulfilled when $b = 0$. Increase in q with decreases in stock size are given by values of b smaller than 0, and in the limiting case where $b = -1$, C/f will remain constant, or may fluctuate independently of stock size.

Results and Discussion

Seasonal fluctuations of catchability

A clear seasonality was found in the fluctuations of the catchability coefficient in the Peruvian anchoveta fishery. This is particularly visible from 1960 through 1971 (Fig. 1) where, on the average, catchability was lowest during the austral winter (July-August) and was highest during the austral summer (November through March). Over this period the minimum recorded values are those corresponding to June 1967 and to July, September and October during the 1965 "El Niño" (q values of 0.0991, 0.0253, 0.0621 and 0.1159×10^{-7} , respectively). Maximum values of q during this period occurred prior to another "El Niño" year, in November and December 1971, and in March 1969 (q values of 1.0993, 1.4258 and 0.9635×10^{-7} , respectively).

These seasonal fluctuations changed and blurred to some extent after the 1972 collapse of the anchoveta fishery. On the average, the catchability coefficient increased dramatically in all seasons, but it became much higher during mid-spring (October-November) and fall (April-June). This strongly influences the overall seasonality pattern when the whole 23 years of observations are taken into account (Fig. 2) where two peaks in the average catchability values occur during mid-spring (November) and fall (March-June) with lower values in mid-winter (July) and early summer (December-February). Also worth noting are the much higher catchability values reported in April 1979, June 1980 and October and November 1979 (q values of 7.1686, 6.5653, 9.3906 and 11.2360×10^{-7} , respectively).

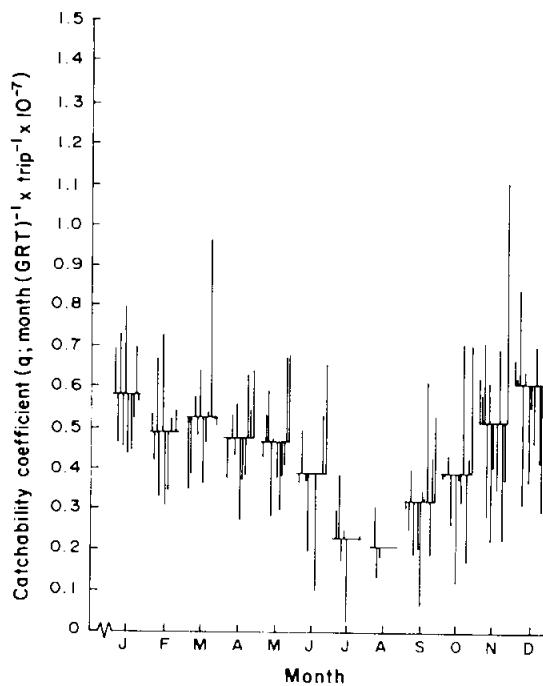

Fig. 1. Seasonal fluctuation of the catchability coefficient (q) in the Peruvian anchoveta (*Engraulis ringens*) fishery between 1960 and 1971. The horizontal lines represent, for each month, the 12-year average value of q , and the vertical lines represent the deviations of the actual values of the observations made each year with respect to the corresponding average.

Las líneas horizontales representan para cada mes, el valor promedio de q para los 12 años, y las líneas verticales representan las desviaciones de los valores observados cada año con respecto al promedio.*

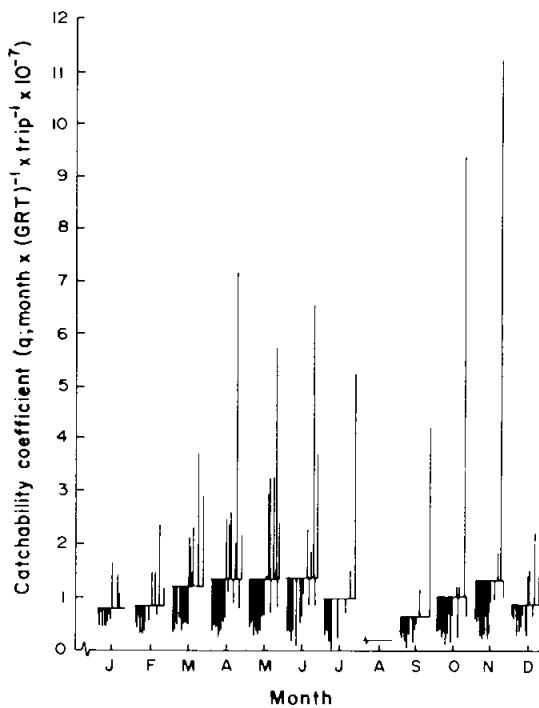

Fig. 2. Seasonal fluctuation of the catchability coefficient (q) in the Peruvian anchoveta (*Engraulis ringens*) fishery between 1960 and 1982. The horizontal lines represent, for each month, the 23 years average value of q , and the vertical lines represent the deviations of the actual values of the observations made each year with respect to the corresponding averages.

*Fig. 2. Fluctuación estacional del coeficiente de capturabilidad (q) en la pesquería de anchoveta peruana (*Engraulis ringens*) entre 1960 y 1982. Las líneas horizontales representan, para cada mes, el valor promedio de q para los 23 años, y las líneas verticales representan las desviaciones de los valores observados cada año con respecto al promedio.*

Over the entire period, seasonality could account for up to $\pm 30\%$ change in the monthly catchability coefficient, which is relatively small in comparison to the year-to-year fluctuation reported so far.

The occurrence of a seasonal pattern is not uncommon in fisheries, and it is obviously related to within-year seasonal changes of environmental conditions (temperature, turbulence, wind stress, etc.) that affect both fishing conditions and the distribution and behavior of fish. If consistent from one year to another, seasonal patterns are relatively easy to handle and do not pose major problems in fish stock assessment and other related analysis. What are troublesome are year-to-year changes in the seasonal pattern, as occurred in the anchoveta fishery in the more recent years. This could have been influenced by the reduced stock sizes and the associated higher catchability coefficients that, as it will be shown below, prevailed after the collapse in 1972. This, however, does not provide a sufficient explanation for the change in seasonal patterns.

A more in-depth analysis of the possible effects of some regulations adopted in the attempts to face the crisis in the anchoveta fishery would need to be undertaken before other natural

causes can be identified. During these years, fishing ports were frequently closed to protect juvenile and/or spawning anchoveta and, in some occasions, juvenile sardines caught along with anchoveta. This more often affected the traditionally highly productive ports in the north, besides limiting the number of observations in some key periods, particularly in summer and winter when the newly recruited and the spawning anchoveta were respectively, more abundant.

Density-dependent catchability

The plot of monthly estimates of catchability coefficient on mean-exploited biomass (Fig. 3) provides a clear evidence that in the Peruvian anchoveta fishery, there was a steep increase in the catchability coefficient with decreasing stock size. The power function proposed by Fox (1974) and MacCall (1976), fitted by a nonlinear regression procedure that uses the search algorithm developed by Marquardt (1963) gives the following estimates: intercept $a = 0.352$ and slope $b = -0.97$, with a correlation coefficient $r = -0.888$. The log-converted linear regression gives very similar estimates for $a (= 0.286)$ and for the slope $b (= -0.966)$ with a correlation coefficient $r = -0.828$, while the geometric mean regression (Ricker 1973) gives estimates that differ slightly ($a = 11.3298$ and $b = -1.17$).

The nonlinear regression method was assumed to produce the best estimates for prediction of q as a function of B . Besides an apparently better fit, it avoids the problems associated with the log conversion needed for the predictive linear regression and the geometric mean methods. The geometric mean could probably have been preferred to account for the expected natural variability in q and B , but it is noted that it is very likely that the two variables are subject to an undetermined observational variability as well, thus making the application of the geometric mean regression less adequate.

A major statistical problem arises from the regression of Y/X on X ($q = C/Bf$ on B , in this case) which, as it is well known, may give a significantly high correlation even if the X and Y values are random variables. This, however, should not invalidate the main conclusions of this

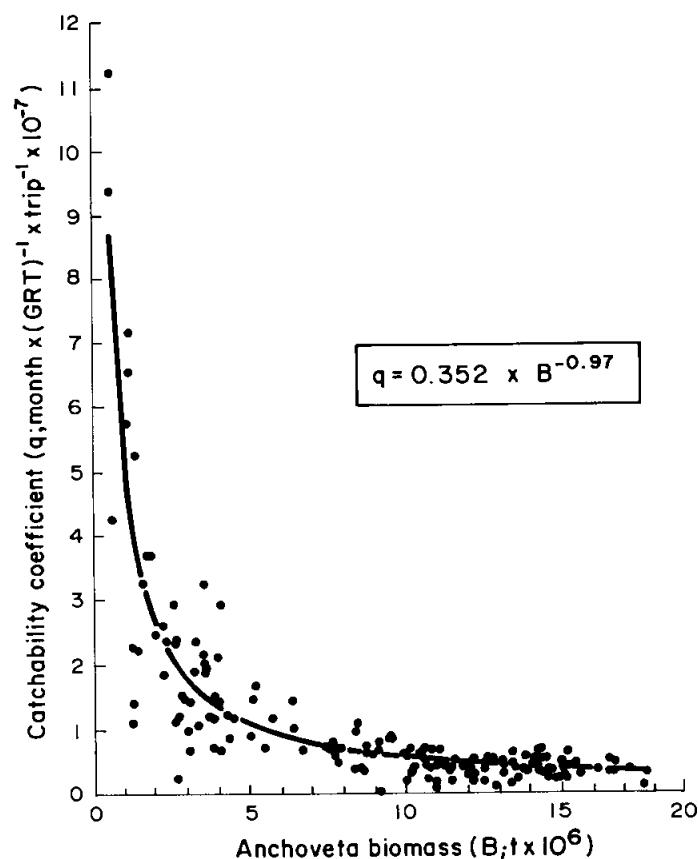

Fig. 3. Relationship between the catchability coefficient and the mean exploited stock biomass of the Peruvian anchoveta (*Engraulis ringens*). The plotted values correspond to the actual observations of catchability and biomass, made each month, from 1960 to 1982, and the line has been fitted by a nonlinear regression procedure.

*Fig. 3. Relación entre el coeficiente de capturabilidad y la biomasa media de la población explotada de anchoveta peruana (*Engraulis ringens*). Los puntos corresponden a los valores mensuales observados entre 1960 y 1982, y la línea ha sido ajustada mediante una regresión no lineal.*

analysis which precisely points at the lack of correlation between C/f and B. The apparent statistical significance of the high correlation coefficient between q and B should, however, be taken with great caution, and it should be recognized that, in this case, the variability and bias of the estimates are unknown, although they may be expected to be relatively small.

With this warning in mind, one can then proceed to incorporate the parameters estimated above into equation (1), by which, in the Peruvian anchoveta fishery the expected variability of the catchability coefficient (q) with stock size (B) would be expressed by:

$$q = 0.352 \cdot B^{-0.97} \quad \dots 3)$$

The curve generated by this equation is shown in Fig. 3 together with the observed values of q and B. The same equation has also been used to estimate theoretical values of q and corresponding values of fishing effort (f) for the months when original estimates or observed values were missing (see estimates in parentheses - Tables 3 and 5), thus allowing the completion of the whole set of monthly estimates of nominal catch (C), biomass (B), fishing effort (f), fishing mortality (F) and catchability coefficient (q) for possible further analyses.

The relatively low value of the slope (b, being very close to -1) and the model below resulting from equations (2) and (3) above:

$$C/f = 0.352 \cdot B^{0.03} \quad \dots 4)$$

indicate that there is a very poor correspondence between the catch per unit of effort estimates used so far and the anchoveta stock size, and that except for stock sizes very close to 0, one should expect catch per unit of effort to remain constant, or to fluctuate independently of stock size. This is clearly illustrated in Fig. 4, where the flat-topped curve generated with equation (4) is shown together with the scatter diagram of observed monthly values of catch per unit of effort and anchoveta biomass.

From this, it can be concluded that there is a very poor relationship between the estimated fishing mortality and fishing effort expressed in terms of GRT-trip. It also follows that for the anchoveta fishery, the catch per GRT-trip is useless as an index of abundance, and should not be applied within this context for stock assessment purposes. This partially justifies the decision taken by IMARPE back in 1972 to abandon the use of fishing effort-based production models for the assessment of the Peruvian anchoveta.

The strong compensatory relationship between q and B is, to a great extent, a consequence of the shoaling behavior through which, even if in low abundance, anchovies and other small pelagics would still tend to aggregate in shoals of a given size. This could, in theory, allow

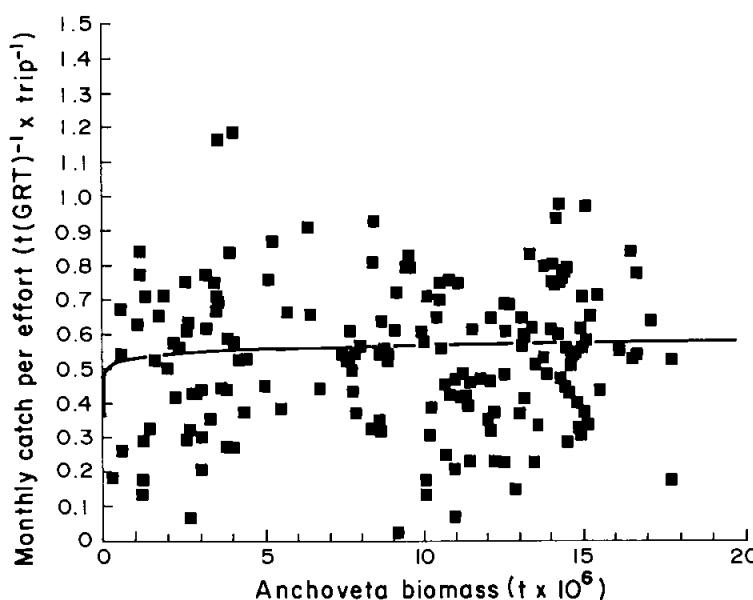

Fig. 4. Scatter diagram of the relationship between catch per unit of effort and biomass of Peruvian anchoveta (*Engraulis ringens*), by month between 1960 and 1982, with theoretical curve generated by equation (4) (see text).

Fig. 4. Diagrama de dispersión de la relación entre la captura por unidad de esfuerzo y la biomasa de anchoveta peruana (*Engraulis ringens*), por meses entre 1960 y 1982, y curva teórica generada con la ecuación (4) (ver texto).

the catch rates to remain relatively high even while catching the last very few fish in a population, provided they are shoaling together and could be detected by the fleet. The fleet, on the other hand, has usually the capacity to increase its fishing power without this being reflected by an increase in nominal fishing effort. This has been particularly the case with the Peruvian anchoveta fishery. By using the GRT-trip as a unit, the nominal fishing effort cannot account for, or reflect changes or improvements introduced on an *ad-hoc* basis (i.e., when abundance was low) to maintain catch rates. In fact, there are indications that as the stock size decreased, the duration of the average trip increased, and so did the time, spent searching, the number of hauls per trip, not to mention the improvements in the cooperation amongst vessels and scouting. This necessarily made the original GRT-trip less valuable as a measure of real fishing effort, and partially explains the increase in q .

Low-cost abundance indexes are, however, always useful for monitoring and assessment purposes, and for future use it might be worth exploring the value of measurements of fishing effort that would more readily reflect changes in the real abundance of the anchoveta stock. Log-book information on number of hauls, fishing hours per trip, searching time (including scouting), etc., could be used to improve fishing effort estimates, which could be further corrected to account for changes in distribution and local abundance. This could be achieved by stratifying catch and effort data by geographical subareas in such a way that, once weighed by the size of the subarea, catch per unit of effort values for each subarea could be added together. The size of these subareas should be kept as small as allowed by the basic information, and the grids of 30' latitude by 10 miles parallel distance from the coast (called "areas isoparalitorales" by IMARPE) introduced together with the log-books in use in the mid-1970s might be a reasonably starting point.

One serious implication of the depensatory relationship represented by equation (3) is that the relationship between stock size, catch per unit of effort or equilibrium yield and fishing effort is no longer expected to be a straight line or a parabola, as is usually assumed in the simplest applications of fishing effort-based production models. If equations (1) and (2) are incorporated in the formulation of a simple production model, for values of $b < 0$ there is a range of values of fishing effort for which there are two equilibrium values of stock size (only one of which is stable), and the relationship between fishing effort and stock size, fishing mortality or equilibrium yield take all the form of backward bending curves. The departure from the traditional straight lines or the parabola will be greater, and backward bending more pronounced as the absolute value of b increases.

Figs. 5 and 6 represent the scatter diagrams of the relationship between estimated anchoveta total catch and mean anchoveta biomass with the corresponding values of fishing effort by year, between 1960 and 1982 (values compiled from Tables 1, 2 and 3). The same figures also show simulated curves of the theoretical relationship between equilibrium catch and fishing effort (Fig. 5) and equilibrium biomass (for two reference levels of virgin stock size) and fishing effort (Fig. 6) when the slope $b = -0.97$ is used in a depensatory version of a simple surplus production model. In the simulations mentioned above, a slope $b = 0$ will necessarily generate a perfect parabola in Fig. 5 and descending straight lines in Fig. 6 (more details about the other parameters used in the simulations follow).

The implications of this type of depensatory relationship for fishery monitoring and management are that, if gone unnoticed, fishing effort may be allowed to increase until the critical point at which the curve bends backwards is reached. From this point on, total catch will inevitably decrease and, contrary to what might be expected, fishing mortality would continue to increase and stock size to decrease, even if nominal fishing effort is reduced. One consequence is the switching of the system from an equilibrium path at a finite population level to an extinction path, from where the only way out, provided other conditions remain constant, is a massive reduction in fishing mortality.

This critical point on the backward bending of "depensatory" curve occurs (see also Csirke 1988) when the ratio between the mean biomass (B) and the virgin stock size (B_∞) is:

$$\frac{B}{B_\infty} = -b/(1-b) \quad \dots 5)$$

If $b = -0.97$ in the Peruvian anchoveta fishery, this critical point would have been reached with a mean biomass reduction to approximately half the virgin stock size ($B/B_\infty = 0.49$). From

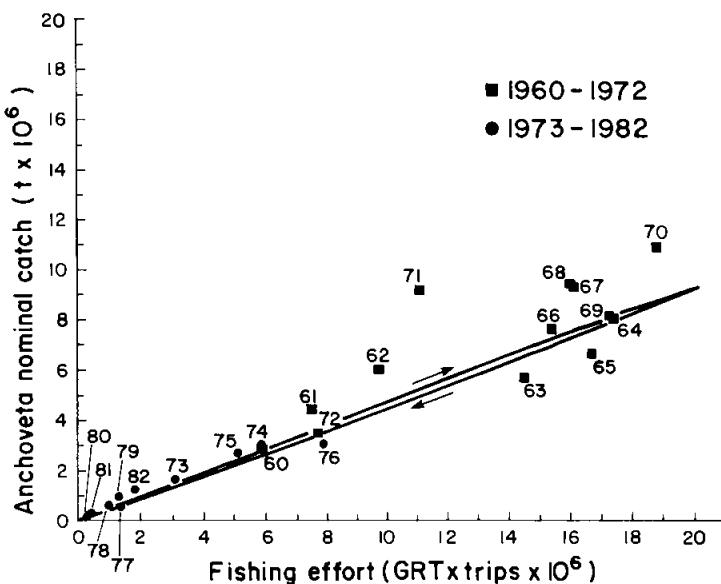

Fig. 5. Scatter diagram of the relationship between total catch of Peruvian anchoveta (*Engraulis ringens*) and corresponding fishing effort by year from 1960 to 1972 (squares) and 1973-1982 (circles), and theoretical curve of equilibrium catch and fishing effort generated by simulation with a depensatory surplus production model incorporating parameters from equation (3) (see text).

Fig. 5. Fig. 6. Diagrama de dispersión de la relación entre biomasa ($B_n, n+1$) de anchoveta peruana (*Engraulis ringens*) y valores correspondientes de esfuerzo de pesca (f_n) por años (n) entre 1960 y 1972 (cuadrados), y 1973-1982 (círculos), y curvas teóricas de la relación entre biomasa de equilibrio y esfuerzo de pesca generadas mediante simulación con un modelo depensatorio de producción excedente incorporando los parámetros de la ecuación (3) y dos niveles de referencia del tamaño de la población al estado virgen (ver texto).

the available biomass estimates it seems that the anchoveta stock was probably pushed close to, but still maintained above this critical point during the late 1960s and early 1970s. However, it surely flipped down well below this level with the advent of the 1972-1973 "El Niño".

Although heavy fishing continued for some time after the collapse, overall fishing pressure on the anchoveta stock has diminished. The stock, however, failed to recover. This, together with the changes in abundance of other predominant species in the Peruvian upwelling ecosystem leads to consider the possibility of more consistent and long-lasting changes affecting the anchoveta ecosystem, as opposed to the also noticeable but relatively transient effects one usually would expect from reversible fishing or environmental events alone.

In the scatter diagram of the relationship between mean biomass and fishing mortality presented in Fig. 7, the data point corresponding to 1972 (mean 1972-1973 biomass) stands as a cut-off point for splitting the observations into two groups, each one of which could be fitted by a straight line - one for 1960-1972, and the other for 1973-1982. The fitting of two lines by linear regression give for 1960-1972 an estimate of the intercept $a' = 16.70 \times 10^6$ and the slope $b' = -7.95 \times 10^6$, with a correlation coefficient $r' = -0.798$, while for the years 1973-1982 the estimates are $a'' = 3.93 \times 10^6$ and $b'' = -1.72 \times 10^6$, with $r'' = -0.630$.

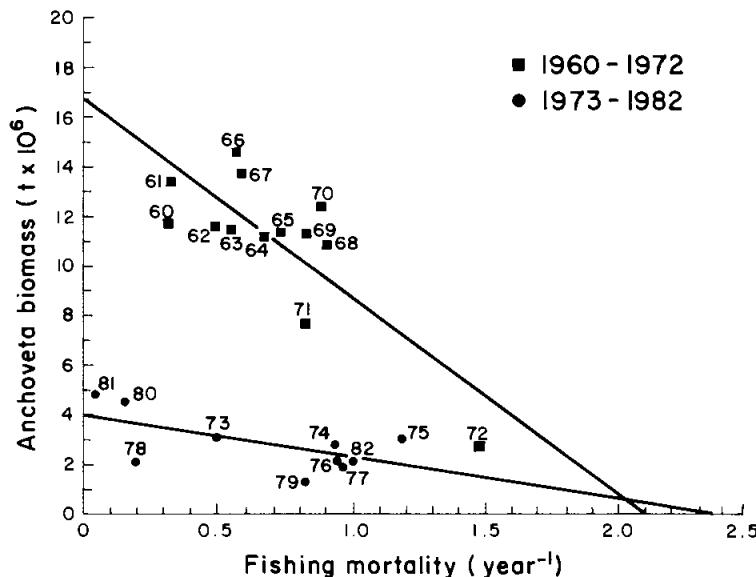

Fig. 7. Scatter diagram of the relationship between biomass ($B_n, n+1$) of Peruvian anchoveta (*Engraulis ringens*) and corresponding fishing mortality (F_n) by year (n) from 1960 to 1972 (squares) and 1973-1982 (circles), and lines fitted by linear regression to both groups of years.

Fig. 7. Diagrama de dispersión de la relación entre biomasa ($B_n, n+1$) de anchoveta peruana (*Engraulis ringens*) y correspondiente mortalidad por pesca (F_n) por años (n) entre 1960 y 1972 (cuadrados) y 1973-1982 (círculos), con rectas ajustadas para ambos grupos de años por regresión lineal.

The fact that the relationship between biomass and fishing mortality can easily be divided into two clearly identifiable series (one up to the collapse of the fishery in 1972 and the other after the collapse), is an indicator of a possible major change in the system of the Peruvian anchoveta, which modified the carrying capacity and thus the reference level of the virgin stock size (B_∞) for the anchoveta in this area. Since in terms of surplus production modelling the intercepts in the biomass axis in Fig. 7 (a' and a'') correspond to the virgin stock size, one may have a rough indication of the relative magnitude of this change. It is also worth noting that the intercept of the two lines in the fishing mortality axis ($c' = 2.10$ and $c'' = 2.28$) almost coincide. In the production model formulation these values correspond to " r_{\max} " the intrinsic rate of instantaneous increase in the population at density approaching 0, and since in both cases this has remained more or less the same, this could mean that the intrinsic characteristics of the stock are the same, although the "surroundings" (i.e., the carrying capacity) had changed.

The estimates mentioned above ($B_\infty = 16.70 \times 10^6$, $B''_\infty = 3.93 \times 10^6$ and mean $r_{\max} = 2.2$) have been used in the simulations referred to above and shown in Figs. 5, 6 and 7. The information contained in these plots is not conclusive, but together with other evidence of changes starting in 1972 (see e.g., Senocak et al., this vol.) do contribute to support the idea that the Peruvian anchoveta stock has switched to a new population path with a much lower maximum equilibrium level.

Abstract

Following a brief review of the adaptations of anchoveta (*Engraulis ringens*) to its highly variable upwelling ecosystem, the hypothesis is presented that the anchoveta stock off Peru consists of a large number of local subpopulations of which each is genetically adapted to "home" to a different upwelling plume, and to spawn during a specific period of the year.

The impact of selective overexploitation of the most productive of these subgroups is discussed in analogy to Pacific salmon and Atlanto-Scandian herring, and the implications for management and research are outlined.

Resumen

Luego de una breve revisión de las adaptaciones de la anchoveta (*Engraulis ringens*) a su altamente variable ecosistema de afloramiento, se presenta la hipótesis que el stock de anchoveta frente al Perú consiste de un gran número de subpoblaciones locales, cada una de las cuales está genéticamente adaptada a su "hogar" en una pluma de afloramiento diferente y desovan durante un período específico del año.

Se discute el impacto de la sobreexplotación selectiva de los subgrupos más productivos, en analogía con el salmón del Pacífico y el arenque del Atlántico-Escandiano y se esbozan las implicancias para su manejo e investigación.

Introduction

The meteoric rise of the Peruvian anchoveta fishery has been well documented. From minuscule catches prior to 1956-1957, the annual yield rose almost linearly to the end of 1970-1971, whereupon the catches fell from about 10 to about 4 million tonnes (Valdivia 1978), while the corresponding stock sizes declined even more. A drop from the previous high population levels was already suspected in 1960 by Saetersdal et al. (1965) who developed a corrected index of catch/effort proportional to stock size and demonstrated a reduction of 50% between the 1959 and 1962 levels of abundance.

In 1973, the total stock was estimated to be around 4 million tonnes while the catch varied from 2 to 3 million tonnes. In spite of the very small spawning stock in these years, there was a spectacular rise to biomass of 12 million tonnes in 1976 followed by an unprecedented crash to 1.9 million tonnes by early 1977, the lowest level of abundance recorded to the end of the 1970s (see Pauly and Palomares, this vol. and contributions in Pauly and Tsukayama 1987a).

Many different explanations have been offered to explain these oscillations in biomass and the overall decline of the anchoveta stocks. However, they can be referred to one of two

^aEditors' note: This is a slightly edited and updated version of a contribution presented at the USA/USSR Conference on Upwelling, Moscow, 8-18 October 1979, which had remained unpublished and which we include here because it contains concepts that are still highly pertinent.

categories: (i) environmental changes, such as those related to the El Niño events of 1957, 1965, 1969, 1972 and 1976, have been linked causally to declines in abundance; and (ii) withdrawals by the fishery as the principal cause of reduced levels of anchoveta abundance and observed increase in abundance of other components of nekton, especially sardines.

This paper attempts to propose a third, alternative explanation and a synthesis of previous ones. The basic premise is that the genetic structure of the anchoveta population has been altered by the sustained removals of about 10 million tonnes annually during the first half of the 1960s. Perturbations of the environment, therefore, now affect the stock in a different manner than prior to the onset of the fishery. It has been known for sometime that stressed clupeoid populations signal this by violent and rapid fluctuations in numbers concomitant with alterations of other vital parameters (Murphy 1973).

The mechanism whereby this is effected is the selective removal of the segments of fish forming peaks of abundance, such as during time of spawning, and which possess the highest reproductive potential. The remaining spawning stocks are therefore deficient in number and inefficient spawners. However, such a hypothesis cannot be sustained without an auxiliary one, stating the independence or semi-independence of a large number of subgroups constituting the overall anchoveta population. The argument is developed in analogy to that for anadromous salmonid species in the North Pacific, i.e., based on a racial stock concept and home stream theory.

The Peruvian Stock of Anchoveta

The range of distribution of *Engraulis ringens* extends from 4°30'S to 42°30'S, using the most distant places of occurrences as boundaries. This represents a linear extent of almost 4,000 km. The offshore distribution varies not only with the season but also with the configuration of the continental shelf and its width. The edge of the shelf may be placed at 200 m isobathylne. But even within this very narrow coastal shelf, most of the anchoveta are found within 60 km off the coast, and the bulk of the commercial catch have been made in the past within 10 km off the coast.

The temperature regime varies less than what could be expected over such a wide geographic range, primarily due to the upwelling along the Eastern Boundary Current which flushes the shoreline with waters of 16°C or thereabouts. Temperature limits can be set at 14°-19°C, but they are by no means well defined and can be exceeded, especially in the upper range.

Besides this two-dimensional dimension of the anchoveta's ecosystem, largely set by temperature, there is a vertical boundary set by the oxygen content. Below 40 meters depth on the shelf, the undercurrent is low in oxygen, generally less than 2 ml/l and diminishes rapidly with depth. Echograms fail to confirm large concentrations of anchoveta below 40 m or in waters with 2 ml/O₂/l. Most schools have been detected in depths from 20 to 40 m (Villanueva 1970).

The heaviest concentrations of anchoveta are found outside northern and central Peru. In the north, the abundance drops off quickly while in the south, it trails off gradually (Pauly and Tsukayama 1987b). But even within the optimal distribution range, sharp density gradients occur. The definitions of these can either be done visually from echograms, as was done from 1964 to 1972 or thereafter from integrated echo outputs. An example is given in Fig. 1 (left map), which is based on charts from Johannesson and Robles (1977). The mapping was done in February during the austral summer spawning season and the density chart clearly indicates the presence of isolated density centra. They are interpreted here as manifesting the existence of distinct subgroups, which are, to a large extent, isolated spatially during the spawning season.

This is contrary to the prevailing stock concept which postulates few but very large subpopulations based on meristic characters, especially vertebral counts. Brandhorst et al. (1965) thus separated the Chilean anchoveta into a northern and a southern group. Jordan (1963) failed to detect any differences in the population along the entire Peruvian coast. Tsukayama (1966) found that the average number of gill rakers for fish caught at Chimbote in the north differed from that established for samples from Mollendo in the south. Likewise, Rojas de Mendiola (1971) found that length of the intestine relative to body length was greater in northern than in

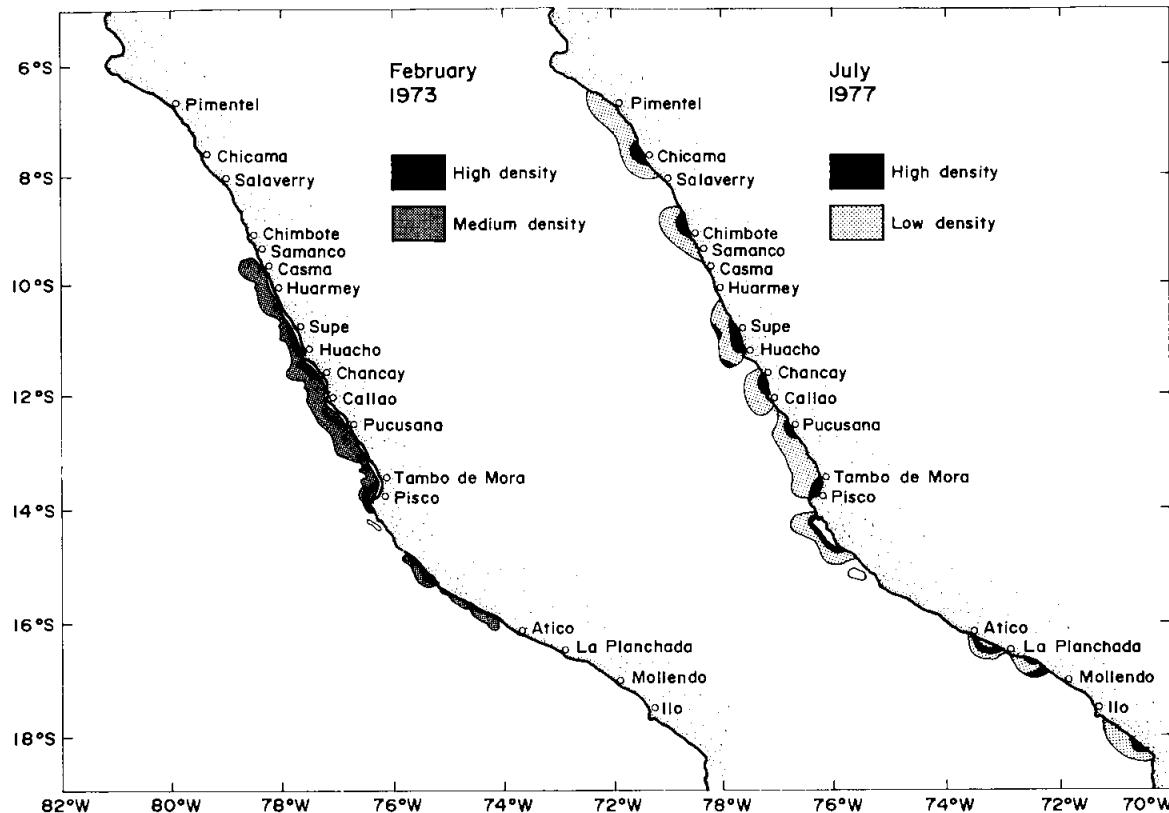

Fig. 1. Distribution of anchoveta during period of high (left) and of low (right) abundance. southern Peru and Chile. This in itself may point to a heavier component of zooplankton in the diet of the southern groups of anchoveta (see Pauly et al., this vol.).

However, for these large population units to represent a common gene pool, there must be free interchange of individuals and no reproductive barriers, neither spatial nor temporal. Some tagging experiments suggest rather long and rapid migrations, but there is a question as to what extent anchoveta tagged with an internal magnetic tag exhibit their normal behavior pattern. The most pronounced relocation of fish occur during El Niño events when the warm water from the north leaves the fish only two choices, either to retreat to the narrow coastal strip where upwelling maintains temperature within their tolerance limits or to migrate south. Valdivia (1978) reports that large numbers of anchoveta in 1972 were found only south of 10°S in March, south of 12°S in April and finally south of 15°S in the beginning of May. But a rapid southward retreat of this type does not guarantee that the relocated fish will successfully spawn in their new environment.

The opposite is a more likely event: independence of population units can be identified and established just as well from spawning time as from meristic characters. Anchoveta can spawn during the entire year, but practically speaking, spawning occurs for eight or nine months, from July to March. Within this time span, one can identify two periods, one during the austral spring from September to October, and a less intense spawning period in January–February (Senocak et al., this vol.).

It has been claimed by Paulik (1970) that the same anchoveta can spawn both in spring and, six months later, in the summer. However, there is no direct evidence to substantiate this^a.

^aEditors' note: this was a valid point when the original version of this paper was written. By now, evidence to substantiate this is available (see references in Pauly and Soriano 1987). However, the author's main point is not affected by this.

Rather, the fact that the spring spawners are consistently two or more times more abundant than the summer spawners testifies to the independence of these two spawning units. In the catches made during or shortly after spring spawning, the mature fish dominate while the immature fish represent the strongest group in catches after the summer spawning. On the average, there must be factors or conditions during the spring spawning which render this the most successful of the two. In the course of the evolutionary process, this must then eventually manifest itself genetically.

This process has been going on for the last 11,000-12,000 years. Studies of sediment cores from a shelf region of 14°S turned up anchoveta scales in all layers as well as scales of hake. In contrast, sardine scales were present only intermittently and for relatively short time periods. No periodicity or regular patterns were detected between the sardine periods. The anchoveta scales account for 79% of all scales, hake for 16% and sardines less than 2%. Other groups were of very little significance (DeVries 1979; DeVries and Pearcy 1982).

During this long history, the anchoveta has maintained itself in the coastal waters. If scale abundance at different times are taken to reflect changes in population size, there would be of the order 1:5, based on a time scale of several centuries. No finer solution was possible, and no statements can be made regarding annual or short-term variability, such as observed during the last decade where changes have been of the order 1:10.

Originally, the Eastern Boundary Current was thought of as a rather stable environment. However, intensive studies by the Instituto del Mar del Peru (IMARPE), under the US Coastal Ecosystem Upwelling Analysis Program (CUEA), and by expeditions from the USSR, the Federal Republic of Germany, Canada and other countries, have shattered this concept. The strength of upwelling is not only governed by the wind force, but also by the deep undercurrent (Smith 1978). El Niño events are occurring more commonly than previously believed (Quinn et al. 1978). However, irrespective of the cause and nature of the perturbations, the anchoveta has maintained itself during millennia. The species must, therefore, have developed survival mechanisms or a resilience sufficient to overcome the variability of its ecosystem. This does not carry as an unescapable consequence population numbers should be stable. Rather the species possesses mechanisms to rebuild its population after a temporary environmental setback. This becomes more critical for the anchoveta than for the hake: the former has an average life span of perhaps two years, while it is double or more for hake. One can see this in the scale deposit where the number of hake scales has varied much less than that for the anchoveta over the last ten thousand years.

Several types of evolutionary strategies can be suggested. One would be the development of extremely wide tolerance limits for the physical and chemical factors of the environment as well as high survival rates of different life stages. Another mechanism, suggested by Walsh (1978), is that marine communities may respond to climatic oscillations by a relocation of their center of abundance.

However, there is a growing body of evidence, still largely circumstantial, that a population of fish consists of much smaller subunits than what is termed a "race" in fishery biology, and that other isolating mechanisms exist aside from spatial separation, such as time of spawning. The function of many independent or semi-independent units, many of which are small and perhaps should be termed plus or minus deviants from the strong central groups, is that of buffering against perturbations of the environment. An analogy can be made with a salmon population where the spawning colonies are visible and can be identified in the time-space domain even though they cannot easily, or not at all, be separated by their meristic characters alone. But even within a geographically confined "race", homogeneity of all its members does not exist.

Structure of Exploited Salmon Stocks

The members of the Pacific salmon of the genus *Oncorhynchus* began to ascend the various streams and river systems along the perimeter of the north Pacific Ocean as soon as the glaciers started to recede, some 12,000-13,000 years ago. (This corresponds to about the same time that the anchoveta has occupied the Peruvian upwelling system.) In due course, the genus split into six species, each occupying some specialized habitats, although considerable overlap does occur.

Separation of "races" on the common feeding grounds in the ocean from meristic or serological characters has met with limited success. But segregation occurs on the spawning grounds. Another distinguishing feature is the time of spawning. Thompson (1951) was perhaps the first to decisively point out that the usually bell-shaped time curve or ascendance into a trunk stream and associated peak of spawning essentially reflect survival rates. The center part with highest relative abundance represents the spawners best adapted to the average environmental conditions. If this were not so and reproduction was equally successful at all times during a year, the abundance curve would be a horizontal line. In time, the phenotypically differing units have assumed independence by karyotypic selection. Time of spawning as an inherited character has been demonstrated on several occasions by transplantation experiments.

This of course does not preclude that other factors, such as temperature, affect and alter spawning time in a poikilothermal organism such as salmon. Although changes in mean spawning time have proven to be rather invariant, annual variability is buffered by the presence of plus or minus deviants. By and large, the phenological sequence of events is tightly or loosely coupled, depending upon the variability of the environment; but seen in relation to other aquatic organisms, the variance for salmon "races" is small, which is to be expected in its high latitude environments with pronounced seasonal successions.

Conversely, the diversity of the plus or minus deviants from the mean, i.e., their distance in standard deviation units, expresses the variability of the environment and of the niche to which an organism has adapted itself.

If now a "race" is subjected to commercial exploitation, the brunt of fishing mortality will usually be directed - for purely economic reasons - toward the fish belonging to the peak of the abundance curve. This in turn causes a selective removal of the constituents of the group with the highest reproductive potential. If this process is continued long enough, the net result is a very lowered production. The history of various fisheries provides magnificent examples.

In the Columbia River, the peak abundance curve was July, as seen in 1876 when a gill net fishery commenced (Fig. 2). The heart of this run was removed by the fishery which preferred to operate in July, the month with the best summer weather and the highest abundance of fish. The central part of the run was eventually fished out. The early and late segments of the runs have

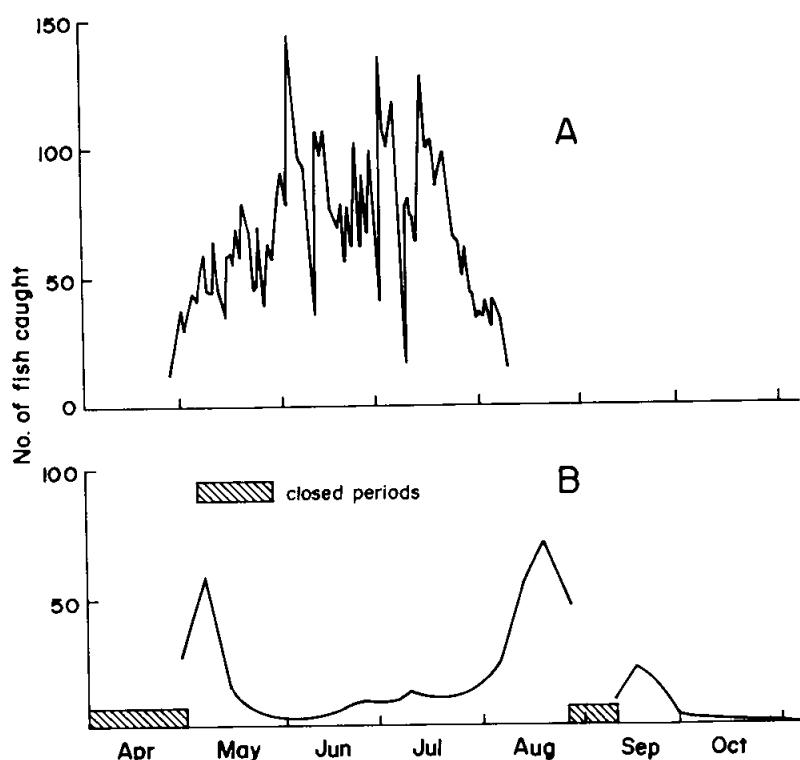

Fig. 2. Seasonal changes of catches of Columbia river chinook salmon (*Oncorhynchus tshawytscha*) (modified from Thompson 1951). A. Daily gill net catches in 1876. B. Catches in 1938, below Bonneville Dam.

Fig. 2. Cambios estacionales en las capturas del salmón chinook (*Oncorhynchus tshawytscha*) del río Columbia (modificado de Thompson 1951). A. Capturas diarias con redes agalleras en 1876. B. Capturas en 1938, Bonneville Dam.

not increased nor filled in the middle part in spite of almost complete protection. Another example is the Karluk River in Alaska where the successive decline of the total stock can be traced very well from the catch records combined with weir counts of escapement. Again, the productive middle part of the bell-shaped abundance curve was destroyed by the fishery (Thompson 1951). The important point is that in both of these two cases, the early or late segments have not increased beyond their historical levels of abundance, in spite of extensive protection from harvesting.

If such a selective fishing pressure continues, not only will the center part of the run diminish, but eventually the plus and minus deviants will diminish because of their low reproductive potential. This is analogous to a fishery of a mixed stock where the marginal groups eventually succumb (Paulik et al. 1967). The end result is that eventually the continuous distribution pattern is broken and the fish appear in geographically isolated small groups with a low net production.

The important question is: Can this stock concept be applied to marine fishes? Superficially, there seems to be no fundamental obstacles to decompose a marine stock, such as herring, into a collection of independent subgroups. Devold (1963) reported that the spawning time of the Atlanto-Scandian stock of herring changed from November to December in 1890 to March to April in 1960 (Fig. 3). He estimated this progressive delay as a few days per year. Over a sufficiently long period of time, this would have the effect of retarding peak spawning time.

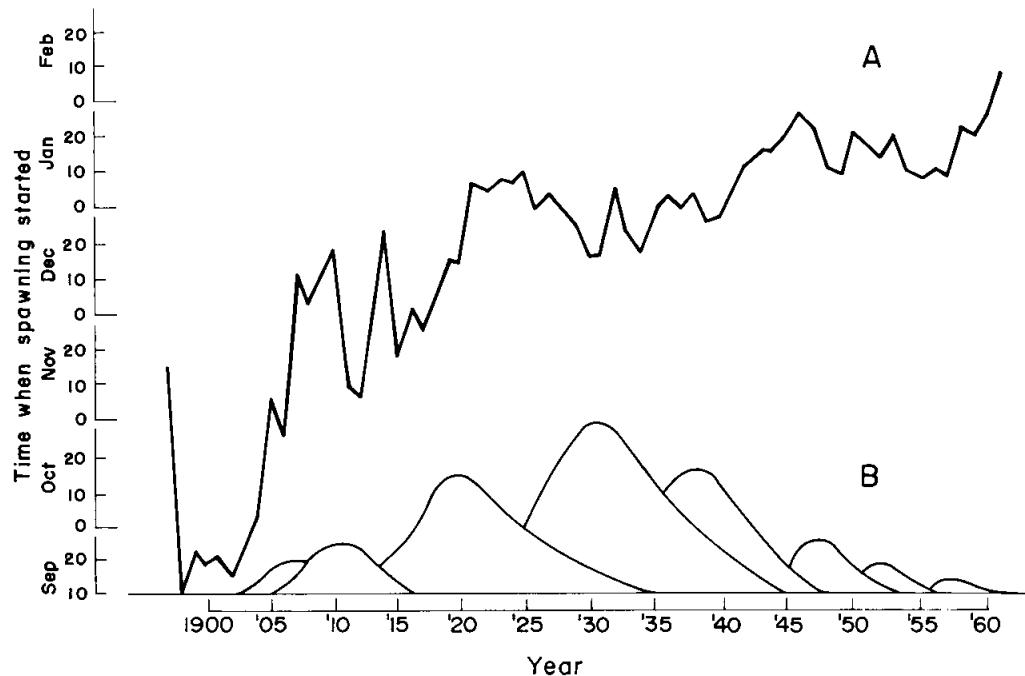

Fig. 3. The continued retardation of first appearance of herring (*Clupea harengus*) on the spawning grounds on the west coast of Norway. A. First day catch of winter herring. B. Decomposition of the original run into a subset of independent groups (modified from Devold 1963).

*Fig. 3. Retardo continuado en la primera aparición del arenque (*Clupea harengus*) en las áreas de desove en la costa oriental de Noruega. A. Captura del primer dia del arenque de invierno. B. Descomposición de la línea original en un conjunto de grupos independientes (modificado de Devold 1963).*

Another interpretation is that the original spawning group consisted of a number of units peaking successively in spawning time from November to March. Since an unrestricted fishery will hit the first segments hardest, they would be the first to go. Later units enjoyed some protection when processing facilities were clogged or overproduction reduced the financial gain from continuous fishing. In time, the early spawning units would succumb and cease to contribute a substantial part of the catch. The fishery would thus turn to the next one and so on with a net result of an apparent shift in peak spawning time as observed in the case of the Atlanto-Scandian stocks of herring.

In order for the homing and spawning time concept to be applicable to the anchoveta, several assumptions must be met. First, there must be a series of independent upwelling plume

with stability to form an identifiable environment. The "home stream theory", as developed for salmon and which refers to fixed geographic localities without specifying the environmental characteristics, must thus be redefined. Rather than referring to geographical terms, the implication for marine species must be that they "home" to water masses or an environment of a certain characteristic with regard to water velocities along all three spherical coordinates, temperature regime, salinity and oxygen distribution to mention some of the obvious attributes.

Next, the fish must be able to maintain themselves in their "home". Also, there must be a distinction in time of spawning (which should be rather short). Finally, the net result of an excessive commercial fishery must create a discontinuous distribution pattern. These aspects will be analyzed next and illustrated with some data generated during the JOINT II expeditions in 1976-1977.

Behavior of Anchoveta in an Upwelling Area

CHARACTERISTICS OF AN UPWELLING AREA

Upwelling is a universal feature along the entire Peruvian coast, but it occurs at rather well-defined, restricted areas. Commonly, several large upwelling areas are recognized, such as the San Juan area, the Callao region and off Chimbote, to mention some. But inside each area, there are a number of plume structures. Two placed in the San Juan region are located about 50 km apart. Upwelled water is recognized commonly by its low temperature, 15.5°-16.5°C, relative to the surrounding water masses (Fig. 4). The subsequent events after upwelled water reaches the

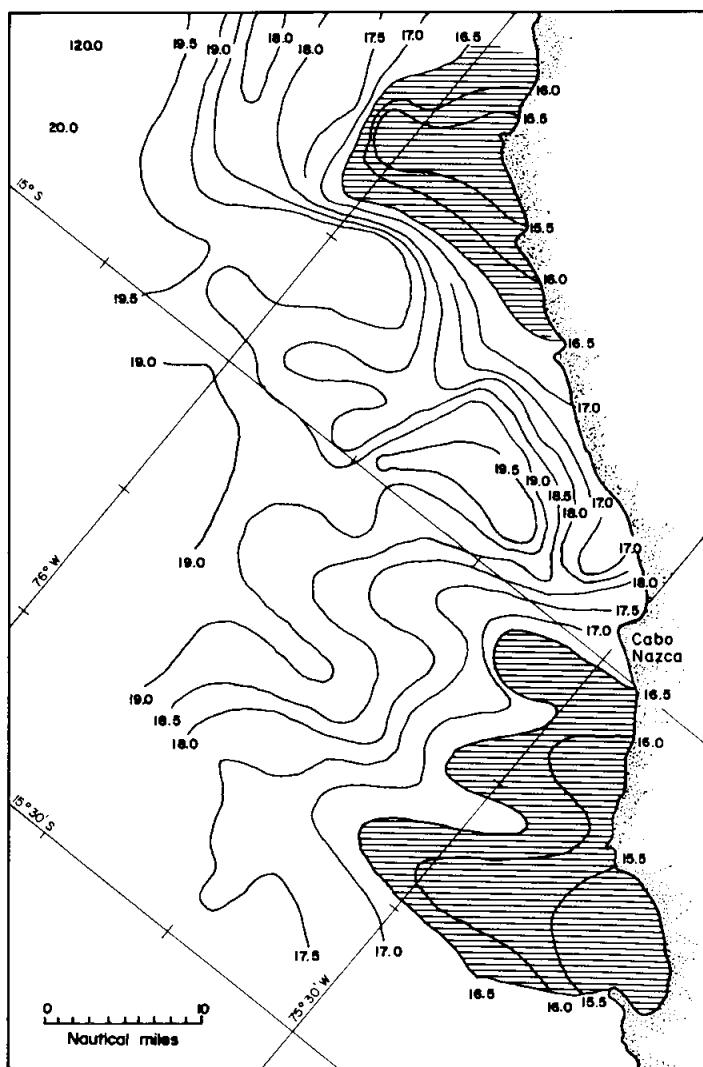

Fig. 4. Surface temperature distribution in the upwelling system around Cabo Nazca, Peru, in March/April 1976 as measured by temperature sensor mounted on an aircraft; shaded areas represent water $\leq 16.5^{\circ}\text{C}$ (simplified from Stuart et al. 1976).

Fig. 4. Distribución de la temperatura superficial de un sistema de afloramiento, tomada por un sensor de temperaturas acoplado a una avioneta. Areas sombreados representan aguas $\leq 16.5^{\circ}\text{C}$ (simplificado de Stuart et al. 1976).

surface are difficult to describe in general terms because of the inherent variability. But generally, the surface water is subjected to an equatorial flow along the coast of 11-12 cm/s velocity and an offshore component of 5-6 cm/s. The component vector is therefore veering away from the coast with a velocity of 12 km/day.

As the surface water flows away from the coast, the temperature rises to 18°-19°C, partly due to heating by the sun. Its nitrate and silica contents are consumed by the phytoplankters; wind mixing might deepen the layer and add more nitrate to the system. Thus we can expect the greatest phytoplankton production to be 10-20 km "downstream" from the plume center.

Eventually, the phytoplankters sink down and re-enter the upwelling area since at a depth ranging from 20 to 100 m, there is a counter current in almost opposite direction to the surface flow with velocities ranging from 5 to 10 km/day (Fig. 5).

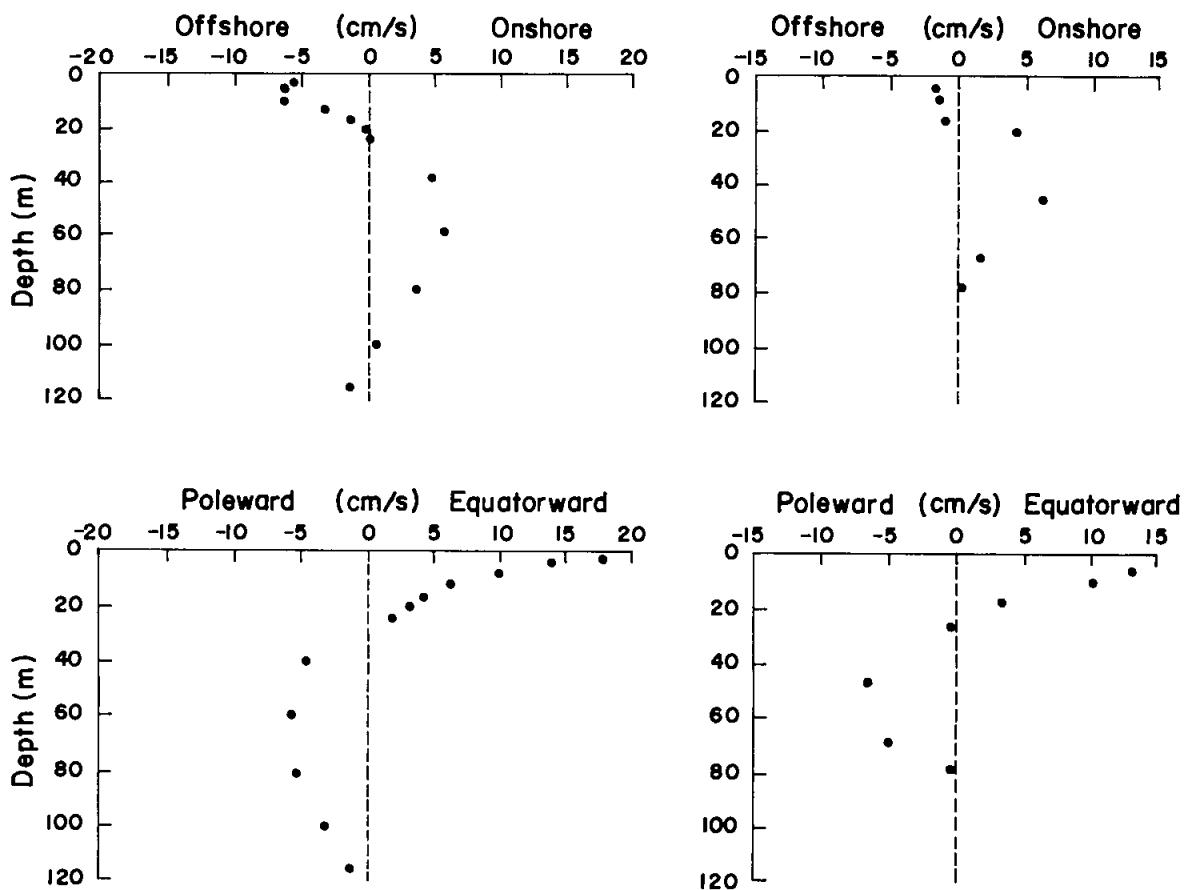

Fig. 5. Onshore/offshore and north/south components of the surface currents at Stations PS/MILA (left) and PPS/AFAVE (right) at JOINT-II area, 22 March to 10 May 1977 (from Brink et al. 1978).

Fig. 5. Componentes hacia la costa fuera de la costa y norte/sur de las corrientes en la estación PS/MILA (izquierda) y PPS/AFAVE (derecha) en el área de JOINT-II, 22 de Marzo a 10 de Mayo de 1977 (de Brink et al. 1978).

If one were to draw successional cycles, zooplankters would follow the phytoplankter shortly, both in time and space. Ammonia released by the excretion of the zooplankter is quickly re-entered in the production cycle through uptake by phytoplankters.

Clearly then, plume structure is governed by the location and bottom topography, but the wind is the prime mover of the plume upwelling and determines both its strength and duration.

It should be noted that the location of plumes may shift; but with the time scale on which anchoveta operates, the individual events are of lesser importance. Only the integrated picture or mean parameters become the important ones. Hence, it is not only permissible but necessary to define a generalized plume structure and a series of upwelling locations. However, a certain degree of constancy of an environment is required to which the fish can adapt itself and "home"

to. A first requisite is that the fish can maintain themselves in a structure of this type with a minimum of expended energy. Diel behavior seems to be one mechanism whereby a closed trajectory can be established in a changing current system.

ACOUSTIC ASSESSMENT OF NEKTON

Echo mapping of the Peruvian anchoveta and other members of the nekton community began in 1964 with visual inspection of the echograms, according to a density classification based on shading or blackening of the echograms (Villanueva 1970). A next major step was absolute quantification through analog integration of the signals over a given distance, such as one nautical mile, and over a specified depth interval. A further advance was the introduction of digital integration which permitted a resolution down to 1-m depth intervals and a time interval down to one single transmission. The latter feature proved to be one of the most useful in determining the density of a school by depth intervals.

The basic data acquisition during JOINT II consisted of a Braincon V-fin towed at the side of the ship extended from a yard arm and with a transducer towed about 1 1/2-2 m below the surface. In the case of hull-mounted transducers, the dead surface space is usually about 5 m or more. The echosounder was a SIMRAD EK 120 and signals were either stored on tape or processed in real time onboard with a PDP 11/10 computer with a basic output after 1- or 5-minute integration by 14 continuous depth zones down to 60 m depth. The data expressed in gm^{-3} were stored on discs and could later be recombined by appropriate computer programs to give densities by volume or by surface unit area.

DIEL FEEDING OF THE ANCHOVETA

It has been known for along time that anchoveta possess a pronounced diel feeding (Pauly et al., this vol.) and migration behavior. The commercial purse seine fishery has taken advantage of this behavior pattern by mainly operating after daybreak, when the fish formed the most dense schools and the anchoveta was most easily captured.

Diel behavior in the JOINT-II area was studied by selecting a square on the shelf with sides one nautical mile long in an area with a concentration of fish. Transecting was continued for 18-24 hours to include the time before sunset, the night and daybreak to noon. Total biomass was expressed as g/m^2 surface and output every minute. If the anchoveta were schooling, this would show up as a few adjacent points with high biomass estimates followed by long periods of near-zero values. During a feeding phase, the schools would break apart and form layers where the individual fish would be filtering while cruising along, and adjacent estimates would all be of approximately the same order. This is well illustrated in Fig. 6 showing the contrast between night and day.

Basically, the schools were dissolved at onset of dusk and the anchoveta commenced feeding singly. This continued during the night until daybreak when dense schools formed. They largely persisted during the day except that the schools started to break apart in the afternoon. One direct interpretation is to see the dense school formation at daybreak as a resting phase after extensive feeding during the night. Then during the afternoon, sporadic feeding commences and the dense schools break culminating in a full-fledged feeding during the nighttime.

More important in this connection is the change in depth distribution, which was explored by using night and day values obtained during transects at the shelf area to insure that mainly anchoveta were insonified. The computer output was, in this case, the average density over one nautical mile expressed in gm^{-3} for the selected depth intervals. The vertical bars in Fig. 7 represent the biomass observed in each depth stratum and converted to a percentage basis in order to make all observations directly comparable. The basic pattern is for the greatest density to be close to the surface at night or at least above 20 m depth. At daybreak when the resting schools are forming, the mean density distribution is normally below 20 m. The ecological importance is immediate. As mentioned earlier, the 20 m depth zone forms the boundary line between the offshore equatorward drift in the top layer and onshore poleward subsurface current.

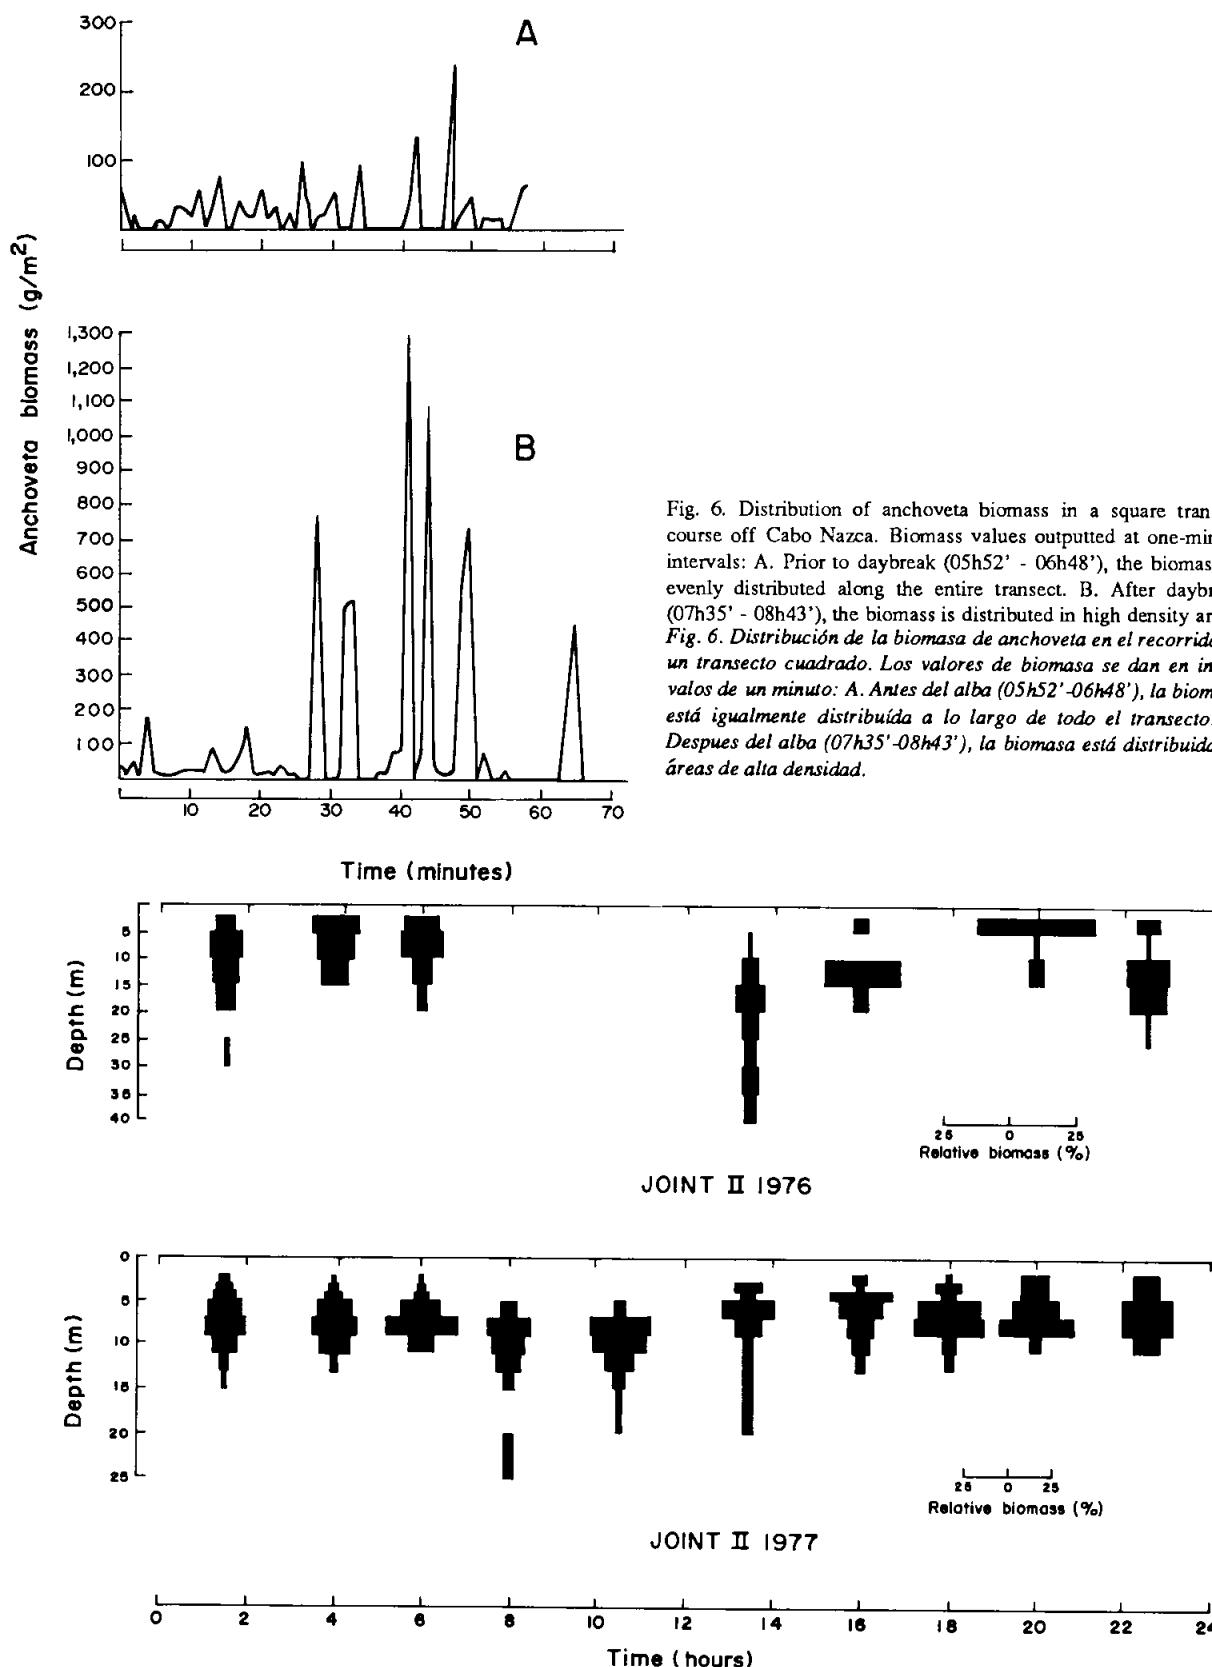

Fig. 7. Depth distribution of Peruvian anchoveta off Cabo Nazca during two 24-hour periods, in March-May 1976 and 1977 (note different vertical and horizontal scales between periods).

Fig. 7. Distribución vertical de la anchoveta peruana frente a Cabo Nazca durante dos períodos de 24 horas, en 1976 y 1977 (nótese las diferentes escalas vertical y horizontal entre períodos).

Since these two component vector velocities are nearly equal in absolute value but in almost opposite directions, the anchoveta can maintain its trajectory with a minimum energy expenditure by alternating its position in the water column.

Some drogue experiments conducted simultaneously show that the drift of a drogue at 10 m was distinctly different from that of a drogue at 35 m. The vertical shearing velocities^a were:

$$\frac{(\delta u)}{(\delta z)} = .411 \text{ cm/s/m} \text{ and } \frac{(\delta v)}{(\delta z)} = .329 \text{ cm/s/m}$$

The 1977 season may serve as a contrast. The anchoveta population fell to an all-time low due to the failure of the fish below 11 cm to survive and to grow to mature size in proper time, and secondly, for the spawners to reproduce successfully. Partly, this must be related to the exceptional hydrographical conditions which existed in 1977. The oxygen distribution in this year prevented the fish from descending deeper than 20 m without exceeding a provisional oxygen limit of 2 ml/l. The depth distribution in this year bears this out, with no anchoveta registered below 20 m (Fig. 7). To aggravate the situation, the high surface temperature forced the fish close to shore where upwelling provided temperatures below 18-20°C. The net result was an exceptional expenditure of energy required to maintain a position in the upper 20 m close to shore or basically within the 50 m contour line. The alternative could be to drift away from shore with the Ekman drift and literally become lost at sea. Both alternatives probably were realized and contributed to the low point of the biomass of anchoveta in 1977.

But in general, the normal behavior pattern of the anchoveta will serve to maintain its position in a geographically restricted upwelling system, which clearly is conducive to the development of a "homing" tendency.

Even more conclusive evidence can be derived from changes in distributional pattern of the anchoveta population which has been subjected to the stress of sustained and intensive commercial exploitation.

RECENT CHANGES IN DISTRIBUTION OF THE ANCHOVETA

The general description of the range of anchoveta is one of a continuous distribution from 5°S to 42°S, but within the heaviest distribution from 6°S to 17°S there exist definite and very sharp density gradients. This could be surmised from the location of fish processing facilities which developed largely during an unrestricted fishery.

The earliest map of density gradients of the anchoveta population drawn from quantified integration values are given by Johannesson and Robles (1977), and their data are summarized in Fig. 1, left side. Although the distribution is almost continuous, there are some very distinct and well-defined high density areas. Schematically, this can be illustrated in Fig. 8a where a series of independent or semi-independent populations overlap and produce an apparent continuous distribution. If the effect of fishing is removal of the best adapted and most productive and therefore, most numerous spawners as alluded to in the case of the salmon, the net result of the rapidly diminishing populations will be a discontinuous distribution with isolated cells or pockets of fish, as illustrated in Fig. 8b. This appears to be very much the case as illustrated by the distribution map produced in March/April of 1977 (Fig. 1, right side). But in addition to the very disjointed distribution, the very striking fact is that the locations where fish were found largely corresponds to the places where a processing facility developed in the early days of the fishery and presumably where the supply of fish was best and most consistent.

In addition to the geographical separation, there is also a temporal separation. Historically, there have always been two spawning populations, one consisting of spring spawners, which spawn in September-October and one group of summer spawners in February-March. The strength of the former was usually twice to thrice that of the latter (see Senocak et al., this vol.). They also differed in age composition with the total biomass in September to be dominated by mature fish. The reverse was true for the summer spawners where the immature fish, spawned six months earlier and now with a length of less than 11 cm, dominated the catch.

^au = Eastward, v = Northward components.

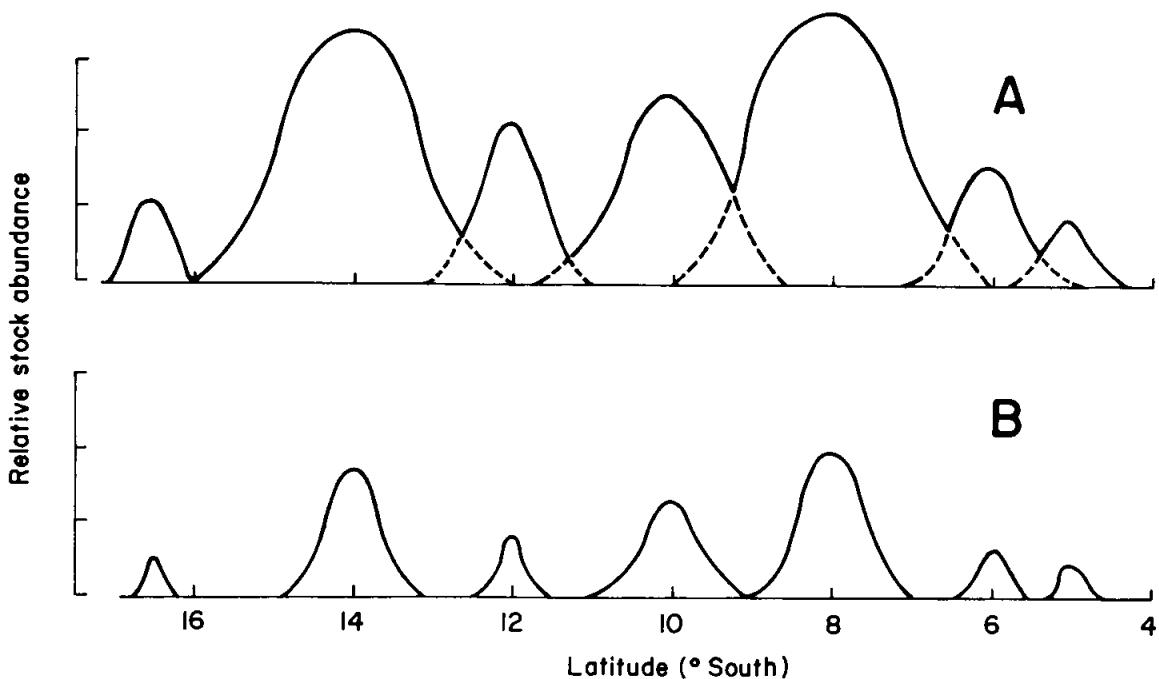

Fig. 8. Schematic representation of the ranges of a series of (A) unexploited (sub)stocks of Peruvian anchoveta, and (B) exploited and stressed (sub)stocks of the same species (see text).

Fig. 8. Representación esquemática de las amplitudes de una serie de (A) (sub) stocks inexploitados de anchoveta peruana y (B) (sub) stocks explotados y fatigados de la misma especie (ver texto).

The mere fact that these differences persist year after year provides the basis which in time will lead to independent groups. One consequence is that the anchoveta basically has one spawning season per year, either in early spring or late summer. In this respect, there has only been an expansion in the time basis. Earlier, the curve of abundance for a group of spawners was taken to reflect differences in survival rate with time. The same argument can be extended to the two principal groups of spawners. The fact that anchoveta can spawn during the entire year, and regularly over an eight-to-nine-month period, does not detract from this argument. There are two time periods when survival is better than the average, and one is decidedly the better one of the two.

If one inquires into the function of the plus and minus deviants, one answer is that they buffer against adversities and perturbation of the environment. The year 1972/73 may be taken as an example when temperatures rose above average for a long time, almost an entire year. As a result, the phenological events of spring spawners were not synchronized and only the summer spawners reproduced successfully (Fig. 9).

Anchoveta and Salmon - a Comparison

An argument has been advanced that the structure of salmon runs and the conduct and effect of harvest on individual salmon "races" have some similarity to and validity for the Peruvian anchoveta populations. But whereas the former exhibits definite spatial and temporal segregation among its various units, in the latter case these boundaries are more vague; areas overlap and events are superimposed.

Ecological efficiency is an attribute which in the evolutionary process demands its price in a closely-knit coupling to an environment. It can only be reached in populations whose environments possess some stability or where the animals have acquired some measure of independence from the environment. Resilience thus becomes a quantity related to the

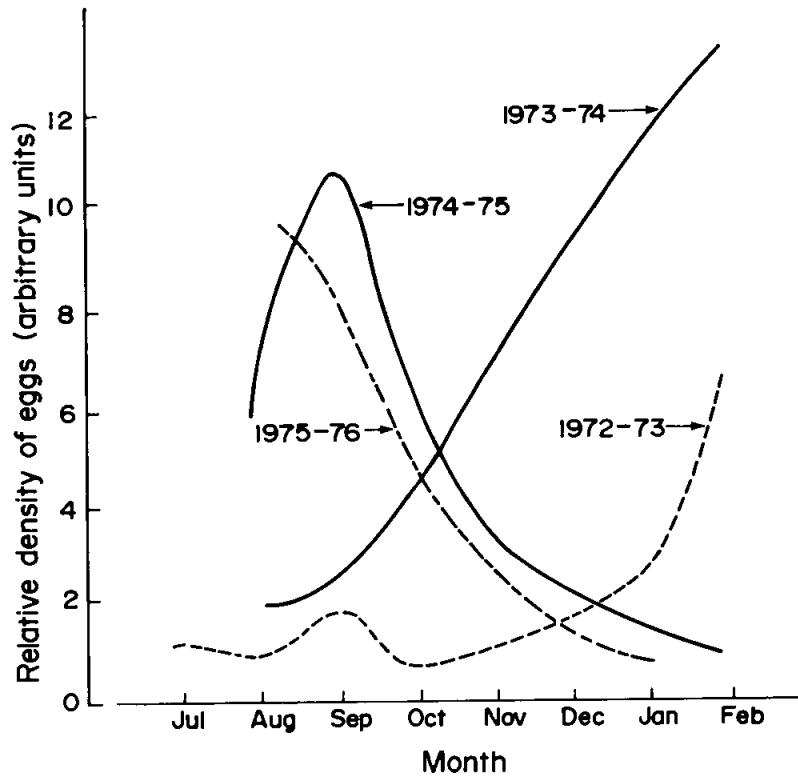

Fig. 9. Alternation between successful spring and summer spawning of Peruvian anchoveta as a result of the temperature anomalies in 1972/1973 (adapted from Valdivia 1978 and Johannesson and Vilchez 1979).

Fig. 9. Alternancia entre desoves exitosos de la anchoveta peruana en la primavera y verano, como resultado de las anomalías de temperatura ocurridos en 1972/1973 (adaptado de Valdivia 1978 y Johannesson y Vilchez 1979).

environmental variability which the animals must overcome in order to successfully reproduce and sustain themselves.

The Peruvian upwelling system is far from stable. The occurrence of El Niño is a common event, although variable in strength and duration (Bohle-Carbonell, this vol.). Research in progress seems to bring out that more profound alterations of the temperature regime and water quality are governed by the deeper undercurrents with both polar and equatorial flow components. Nevertheless, throughout its history during the last 12,000 years, the anchoveta population in Peru has maintained itself.

Some regulatory mechanisms are obvious: separate spring and summer spawners, each group again broken down in many units. The main question is how much interchange there is between these units. Clearly, in the case of the salmon, the evolutionary process has progressed further and the population units have reached a high degree of independence. But even within the various members of the genus *Oncorhynchus* we see different amounts of straying. The extent to which reproduction is successful is usually inversely related to the distance of straying. If a barrier, such as a waterfall is bridged by a fishway, the newly opened territory is quickly occupied and utilized. If a transplantation involves new streams, distance from donor streams becomes a governing factor.

The contention of this paper is that the same principles apply to anchoveta but in a more diffuse form. Thus, the wholesale migration south in 1972 described by Valdivia (1978) did not result in a successful spawning in the new environment (if spawning took place at all). But clearly, some interchange must take place between populations occupying adjacent upwelling plumes and even between temporarily segregated units in the same area. Basically, one must adopt the view that marine populations of fish have not achieved the same degree of adaptation as anadromous species; however, the same structural concepts can be used and the effect of the

fishery remains largely the same. Accordingly then, the decline of the Peruvian stock of anchoveta was accelerated by not only the removal of a large biomass of spawners, but perhaps more, by the removal of the best reproductive units. The doubly stressed population could consequently not withstand the environmental stress imposed in 1972-1973 and 1976-1977, leading, ultimately, to the depressed state of the population today.

An inescapable corollary is that the object of management is not to define a "maximum sustainable yield" or an "optimum sustainable yield", but to prescribe the necessary spawning population. This is by no means a fixed quantity but varies according to the status of the environment and the risk the manager is willing to take. In addition to numbers, the manager must prescribe the characteristics of the fish to be preserved with an emphasis on securing these from the central or most abundant part of the spawning population in each upwelling area.

The future course of fishery science possibly will not be to define management principles but to describe the evolutionary process which enables different components of the nekton to occupy various ecological niches. While the physical environment can be described rather easily through various observable parameters, the independence of nekton units, such as within the Peruvian anchoveta stock, defies the usual approaches. The open question is how the members of a unit recognize an environment essentially which is an imprinting process. In the case of anadromous species, pheromones seem to play a rather important role in local navigation (Nordeng 1971). But the amount of chemical substances is so minute that common analytical tools do not suffice. In most cases, this phenomenon must be studied indirectly by long-term monitoring of both the physical environment and the nekton groups occupying this environment.

Acknowledgements

The Coastal Upwelling Ecosystem Analysis program (CUEA) envisioned and eventually executed a complete study of all energy levels in an upwelling system except for a minor emphasis on nekton. However, through cooperative arrangements with Instituto del Mar del Perú (IMARPE), access was provided to part of the rich material on nekton collected over the years. Credit for use of material from these two sources must be given through the cited papers.

But the stimulating discussions with my colleagues at IMARPE, especially J. Valdivia, the late H. Santander, I. Tsukayama and K. Johannesson, need special mention as well as the members of the CUEA - Nekton component, R.E. Thorne, K.C. Lee, T. Lindem. Special thanks go to L. Brannian, who extracted usable material and prepared graphs for many of the figures.

Abstract

Two alternate classes of mechanisms that could account for evidence of density-dependent growth are introduced: (i) effects of potential linkages of school size with population size, and (ii) effects of size-dependent predation. These may lead to different interpretations with respect to resilience to exploitation, carrying capacity of the habitat, etc., from those implied by the more commonly cited class of mechanisms which involve impact of the population on its food supply.

Resumen

Dos mecanismos alternos que evidenciarían la denso-dependencia del crecimiento son introducidos: (i) efectos de relaciones potenciales del tamaño del cardumen con el tamaño de la población y (ii) efectos de la dependencia del tamaño con la predación. Estos pueden conducir a diferentes interpretaciones con respecto a la repercusión para la explotación, capacidad de carga del habitat, etc., de aquellas implicadas por las clases de mecanismos más comúnmente citadas que abarcan el impacto de la población sobre su suministro de alimento.

Introduction

An apparent dependence of growth on population density is a common finding in studies of the dynamics of natural fish populations (e.g., Beverton and Holt 1957; Ware 1980). The mechanism commonly proposed involves increased competition for available food at high population density.

In the case of small coastal pelagic fish such as anchovies and sardines inhabiting coastal upwelling systems, the extent to which this type of mechanism might really be acting is not clear. For example, Lasker (1970) estimated that at peak population size, the Pacific sardine would have consumed more than the entire secondary production in California's current ecosystems. Nevertheless, no growth increase was noted among adults as the population declined (Murphy 1973). In the similar eastern ocean boundary upwelling ecosystem off Northwest Africa, Mathisen et al. (1978) compared food consumption to food production. Results suggested that food does not directly control the size of adult or recruited fish populations. Mathisen et al. cited Gulland (1971), Murphy (1973) and Steele (1974) as having questioned food limitation as a

control for adult fish "since in those cases where fish have been reduced to a low level through fishing, the structure and size of the next lower trophic level has not changed drastically". In the case of the Peru Current upwelling system, Lasker (1989) estimates that the anchoveta population, at a pre-collapse biomass level of 20 million t, would consume about one-fourth of the primary production of the ecosystem (note that the value "40", rather than "4", in Lasker's published paper is apparently a typographical error). Since anchoveta obviously will consume some quantity of secondary production, the question as to whether it may at times be limited by its food supply is unanswered.

Indeed, Palomares et al. (1987) found a significant correlation between growth performance and population biomass of Peruvian anchoveta over the period 1954-1982. They discussed three different effects which might have increased growth rates as the population declined: (1) decreased competition for available food due to fewer competing individuals, (2) a relative increase in abundance of more nutritious zooplankton, due to lessened competition for food resources and lessened predation by anchoveta, *vis à vis* less nutritious phytoplankton, and (3) a corresponding increased proportion of more efficient particulate feeding on zooplankton relative to less efficient filter feeding on phytoplankton. All three effects fall under the class of mechanisms implying a substantial impact of feeding activity on the amount or composition of the regional-scale food supply. Since natural mortality is generally size-dependent, and therefore growth-dependent, such a directly-linked impact of the population on its own food supply would seem to constitute a powerful compensatory mechanism with respect to effects of fisheries exploitation.

The purpose of this chapter is to point out that plausible alternative mechanisms exist which do not necessarily imply a substantial impact on the large-scale food supply. Two classes of mechanisms will be addressed: (1) effects of school size, and (2) effects of size-dependent predation. These may lead to different interpretations of evidence of density-dependent growth with respect to resilience of the population to exploitation, potential carrying capacity of habitat, etc.

Effects of School Size

Consequences of Fish School Geometry

As fish schools vary in diameter, they may also vary correspondingly in vertical thickness, i.e., large schools may be thicker in vertical dimension than small schools. To the extent that school thickness may vary in rough proportion to school diameter, the areal aspects of the school geometry, such as the surface area encompassing the volume occupied by the school or the cross-sectional area swept by school movement, will vary as the second power of δ (where δ = school diameter or other appropriate characteristic length scale). However, the volume of the school, and therefore, the number of individual fish contained, will vary as the third power of δ . Thus,

$$\frac{\text{school surface area}}{\text{school volume}} \propto \frac{\text{cross-sectional area swept}}{\text{no. of individuals in school}} \propto \frac{1}{\delta} \quad ...1)$$

The consequence of expression (1) is that as δ (i.e., school size) increases, the average supply per individual within the school of food and other substances (e.g., replenished dissolved oxygen where concentration may have been depleted by respiration) that must enter the school interior through the cross-sectional area swept by a moving school (or diffused through the outer surface area of a stationary school) decreases in proportion to δ^{-1} . Thus, a fish in a larger school (of size $\sim \delta_1$) must, in comparison to a fish in a smaller school (of size $\sim \delta_2$), either accept an average food ration which is smaller by the factor δ_2/δ_1 (and to the extent that a school may be capable of depleting the oxygen within the water volume occupied, the additional detriment of a lowered uptake rate of oxygen) or carry the metabolic costs of swimming faster by a factor of

δ_1/δ_2 . Kils (1979) discussed this effect as a factor limiting the school size of the Antarctic krill *Euphausia superba*.

Of course, it is possible that large schools are strictly limited in the vertical dimension by external constraints (water column structure, total water depth in shallow areas, vertical distribution of food organisms, etc.). In the case of a flattened school shape of constant vertical dimension, the volume and the surface area of a school vary nearly in direct proportion. Even so, the ratio of cross sectional area swept to the volume of a moving school would continue to vary as δ^{-1} so long as both horizontal dimensions tend to increase or decrease together (i.e., excluding the case where the length of the school axis parallel to its motion remains constant while school width, normal to the direction of motion, increases.) Actually, Mais (1974) finds seasonal, diurnal, and other (e.g., relation to topography) tendencies for school sizes and for school thicknesses to vary somewhat in phase, such that thicknesses of larger schools of northern anchovy off California tend to be greater than those of smaller schools. However, one finds little information in the literature on school thickness in relation to school diameter; this may indicate a lack of appreciation of the potential importance of school surface to volume ratios with respect to nutrition and metabolism of schooling fish.

Should Average School Size Increase with Population Size?

Pitcher (1986) cites potential advantages of schooling behavior in fish including hydrodynamic advantages, countering predation, discovery of food patches, and opportunities for group learning. In any case, it seems clear that for species with pronounced schooling behavior, individuals or small groups of fish must tend to increase their probability of survival and successful propagation of their genetic material by joining with other conspecific groups of similar body size that might be encountered. Thus, in the absence of processes tending to fragment the school, school size would tend to increase with time. The expected rate of increase depends on the rate of encounter with other individuals or schools; that is, all other factors being equal, it should be roughly proportional to population density, i.e.,

$$\text{number of individuals joining a given school per unit time} \propto P^c \quad \dots(2)$$

where P is the size of the population, and the exponent c ($0 < c \leq 1$) represents MacCall's (1980) suggestion for incorporation of variable habitat size in representing a density-dependent mechanism (i.e., $c = 0$ implies that habitat size varies in proportion to population size and thus, that population density does not vary with population size; $c = 1$ implies that there is no habitat size variation and thus, that population density varies directly with population size; $0 < c < 1$ implies the less-than-proportional increase of habitat size with population size which, for coastal pelagic fish populations, appears to fit observations).

Obviously, processes tending to fragment schools become substantial at some point or the entire population would tend to aggregate into a few very large schools, whereas large numbers of disjoint schools is the observed situation. This implies that, while the tendency for aggregation must dominate when the school size is small, processes of fragmentation must become increasingly important as school size increases, i.e.,

$$\text{number of individuals leaving a given school per unit time} = F(N) \quad \dots(3)$$

where $F(N)$ is some increasing function of N (N = number of individuals in a school), at least over an observed range of school sizes. Combining expressions (2) and (3) yields

$$\frac{dN}{dt} = kP^c - F(N) \quad \dots(4)$$

where k is the constant of proportionality implied by expression (2). Using a formulation equivalent to equation (4), Anderson (1981) added the assumptions that the number leaving was linearly proportional to N (i.e., $F(N) = K N$, where K is a constant) and that the number joining (kP^c) was constant with time. He added stochastic terms to the entrance and exit rates and to the relationship of N to δ . He thereby constructed a model that reproduced the frequency distribution of pelagic fish school diameters off Southern California reported by Smith (1970).

The question of the form of $F(N)$ is an important one. There must be some ultimate limiting point at which the school size becomes too large for its members to meet their metabolic requirements. Upon growing to that point, it would seem that the school must become unstable and break apart. However, Smith (1981) reports a substantial range of school sizes of coastal pelagic fish rather than the tight modal distribution that would suggest that school size is controlled only by the ultimate metabolic limit. Apparently, other processes of fragmentation act over a range of sizes well below that point.

The hypothesis that individuals altruistically leave the school when they perceive that it is becoming too large for peak efficiency appears to be untenable. A principle of behavioral ecology states that animals do not sacrifice their own fitness for the good of their group (e.g., Grafen 1984). Various models (Sibly 1983; Pulliam and Caraco 1984; Clark and Mangel 1984) indicate that the optimum group size is unstable and that group sizes in natural systems are considerably larger than optimal size. This is because individuals do better in a group (even an oversized group), than on their own. Pitcher (1986) draws the analogy to an overcapitalized fishery in which individuals will not withdraw in order to increase the profit of those remaining in the fishery as long as they themselves have not reached the point of zero profit. The effect of natural selection is to ensure that individual fish within a school maximize the probability of successfully propagating their own genetic material relative to that of other individuals in the school. Natural selection would thus act to obliterate this type of altruistic behavior.

Having rejected the hypothesis that altruistic behavior by individuals provides the mechanism for removing fish from a school, it is difficult to envision behavioral responses that would induce other individuals to exit the school while allowing the initiators to stay. The remaining possibilities include stochastic effects such as amplified random motions within a school that might lead to polarized movements in different directions by different segments of a school such that fish in between must relinquish their attraction to one of the segments to stay with the other. The two segments could thereby lose contact, thus splitting the school into two smaller schools. A related effect might occur when two separate food patches are encountered at two sides of the moving school front. Feeding behavior would attract school members to one or the other of the food patches, leading to a similar loss of contact between school segments (Paul E. Smith, pers. comm.). Also, it is possible that predator attack could fragment a school, although Pitcher (1986) emphasizes that the observed tendency under attack is for increased school cohesiveness.

In these cases, the average number of fish leaving a school per unit time should, on average, be proportional to the total number in the school at the time a fragmentation occurs; i.e., $F(N) = K N$ (where K is a constant of proportionality), as assumed by Anderson (1981). With this substitution, the equilibrium solution to equation (4) is $kP^c = K N$, or

$$\text{equilibrium school size } \equiv \tilde{N} = \left(\frac{k}{K} \right) P^c \quad ...5)$$

Equation (5) predicts that average school size will increase with population size provided $c \neq 0$ (i.e., provided population density increases with population size.) In fact, even if k and K are not constants, the two premises: (i) that the rate of entry into a school increases with population size, and (ii) that the rate of leaving the school increases with school size, must lead to an equilibrium that shifts to larger school sizes as population size increases. Of course, the actual distribution of school sizes might reflect large, possibly highly nonsymmetrical, stochastic variability about such an equilibrium.

Mais (1974) found that the discrete daytime schools of northern anchovies off California tended to break up into scattering layers at night. This is in accord with the common pattern for clupeoids (Blaxter and Hunter 1982). This particular type of shift in school size and character does not necessarily imply altruism by individuals, but merely an alteration in attraction and

cohesion due to changes in visual acuity with the drastic day-night change in light. Different values of k and $F(N)$ in equation (4) resulting from the changed attractive and cohesive properties would lead to two different effective equilibrium school sizes depending on day or night conditions. Mais also found that the distribution of school sizes is somewhat dependent on season. Seasonal changes in behavior, food patch size spectra, etc. could result to variations in attraction to the school (i.e., in k) or in cohesiveness (i.e., in $F(N)$) leading to seasonal variation in \bar{N} . He also noted extremely large dense schools forming along steep bottom gradients of submarine canyons or escarpments. In this case, the topographic features could in themselves attract fish (i.e., act to effectively increase k on a very local scale) and provide points of orientation which could counteract the tendency for school fragmentation as a result of random motions of polarized school segments (thereby decreasing $F(N)$). The result would be a corresponding local increase in \bar{N} . In all of these cases, equation (4) could separately apply to each diurnal, seasonal, or local situation, with the net integrated result that average school size in the habitat would increase with population size.

Applicability to the Anchoveta

Jordan (1971) notes that anchoveta form large, dense schools during the daylight hours which break up at night into smaller feeding schools. This may be a simplification of a more complex situation similar to that described by Mais (1974) for the northern anchovy. However, it will be useful to discuss the problem on this basis. In that case, the considerations presented above could act on both scales: (i) in the formation of the large daytime schools from a background "population" of feeding schools, and (ii) in the determination of the size distribution of nighttime feeding schools from the background population of individuals. In both cases, the effective value of P in equation (4) could depend on the total population size and the considerations presented above could thereby hold.

In the case of food ration, the nighttime case seems to be the pertinent situation to consider. In the smaller "feeding schools", a proportional variation of vertical dimension with horizontal dimension is most likely. In a tank experiment wherein relatively large food particles induced the "particulate" (i.e., "biting") feeding response, Leong and O'Connell (1969) found that a 64-fish school of northern anchovies received substantially less ration per unit time at a given particle density than did schools of 16 fish and less. J.R. Hunter (pers. comm.) has observed that anchovies in smaller schools tend to be less polarized in their behavior and more apt to make excursions from the main school trajectory in order to take particles lying outside of the school's main path; in larger schools, the individuals seem more controlled by cohesive behavior and therefore, apt to get less ration per individual.

In the case of oxygen supply, the large densely-packed daytime resting schools may constitute a situation where effects on oxygen uptake affect the ability to metabolize, and thereby utilize for growth, food taken during the feeding period (Pauly 1981). This writer is aware of no measurements of oxygen depletion taken at sea within a school of clupeoids. However, McFarland and Moss (1967) measured oxygen depletion within schools of striped mullet (*Mugil cephalus*). They found a reduction of dissolved oxygen within all schools measured. The magnitude of the reduction correlated with school size, ranging up to 29% (in a school of size $\delta = 150$ m). Actual values of the reduction were in the range of 0.12-0.40 mg L⁻¹ for "small" ($\delta = 4\text{-}9$ m) schools, 0.50-0.80 mg L⁻¹ for "medium" ($\delta = 18\text{-}30$ m) schools, and 0.70-2.10 mg L⁻¹ for "large" ($\delta = 75\text{-}300$ m) schools. Typical separation between fish within daytime anchoveta schools is of the order of one fish length (Jordan 1971) and so comparable reductions in dissolved oxygen concentration seem possible for large anchoveta schools. Brett (1979), in experiments with different fish species, found that a drop of dissolved oxygen of one mg L⁻¹ causes a 30% reduction in growth rate.

Effect of Size-Dependent Predation

Small coastal pelagic fish such as anchovies attract a varied community of natural predators including sea birds, marine mammals and predatory fish. These predators tend to live longer than

their smaller prey, and thus their population responses would tend to lag variations in their food supply. In many systems the predators have access to alternative prey. Switching of predation pressure to these alternate food resources is one likely response to population decline of a major prey species. But, because of the enormous size of the Peruvian anchoveta population prior to the 1971/72 collapse, and its corresponding dominance within the current Peru ecosystem, the opportunities for switching to alternative prey during the decline of the anchoveta might have been more limited than in more diversely populated ecosystems. Thus, predators without an option of migration to other feeding grounds, e.g., sea birds, marine mammals, etc., with strong local affinities, may have to attempt to derive continued sustenance by extracting an increased share of a declining food base.

On the other hand, predator populations that habitually migrate to exploit spatially separate food bases may not have to experience population declines due to decline in one of its major food bases. For example, Muck and Sanchez (1987) consider mackerel (*Scomber japonicus*) and horse mackerel (*Trachurus murphyi*) the most important predators of anchoveta throughout the entire era of high anchoveta biomass and the more recent era of lowered biomass. These fish exploit both the nearshore habitat of the anchoveta and the habitat further offshore. They are opportunistic feeders, shifting to zooplankton and euphausids where anchoveta are less available. In fact, Muck and Sanchez (1987) assume a constant biomass of mackerel and horse mackerel over the entire period of high anchoveta biomass and recent decline, and thereby infer a relative increase in specific predation rate in the recent period.

These considerations suggest a substantial increase in natural predation pressure on the anchoveta, per unit anchoveta biomass, since the decline. If, as suggested in the previous section, school size has also declined, this could further increase predation mortality (if one accepts the argument of Clark (1974)).

Predation mortality is thought to be size-dependent in both larval (Hunter 1971; Folkvord and Hunter 1986; Miller et al. 1988) and juvenile (Parker 1971; Healy 1982; Hargreaves and LeBrasseur 1986) fish. Thus, animals which grow quickly through the various vulnerable stages increase their chances of successful recruitment. Any larva or juvenile which by chance gets access to a better ration or other favorable growth condition thereby acquires an incrementally increased probability of avoiding predation. This effect cascades as the fish grow through the multitudinous series of size increments between hatching and recruitment, with the net result that slower-growing individuals make up a reduced portion of the survivorship as age increases. The mode of the distribution of size at age is shifted toward larger sizes (Fig. 1). Thus, the apparent growth rate computed from samples of survivors would be larger than the true growth rate, merely because of the biased mortality.

For example, Parker (1971) experimented on replicate populations of juvenile salmon in eight separate aquaria each having an identical, continually replenished food density. Thus, the true growth rates should have been identical. In half of the aquaria, three larger salmon were introduced as predators; the other half were kept predation-free as controls. After allowing time for the populations affected by predation to be substantially reduced, all the populations were measured. An increased growth rate of 0.3-0.5% per day was measured in the populations affected by predation, due entirely to the bias caused by size-dependent predation.

If, as suggested earlier, the relative predation pressure was indeed increased during the population decline of the anchoveta, this bias toward larger size at age and corresponding larger apparent growth rate would have been amplified. In such case, there is no need for alteration of actual growth rates to have occurred in order to produce the evidence of density-dependent growth in anchoveta reported by Palomares et al. (1987).

Discussion

Three classes of hypothetical mechanisms for density-dependent growth have been put forth for consideration:

1. Impact of the population variations on the ambient food supply,
2. Effects of linkages of school size with population size,
3. Effects of amplified size-dependent predation during population decline.

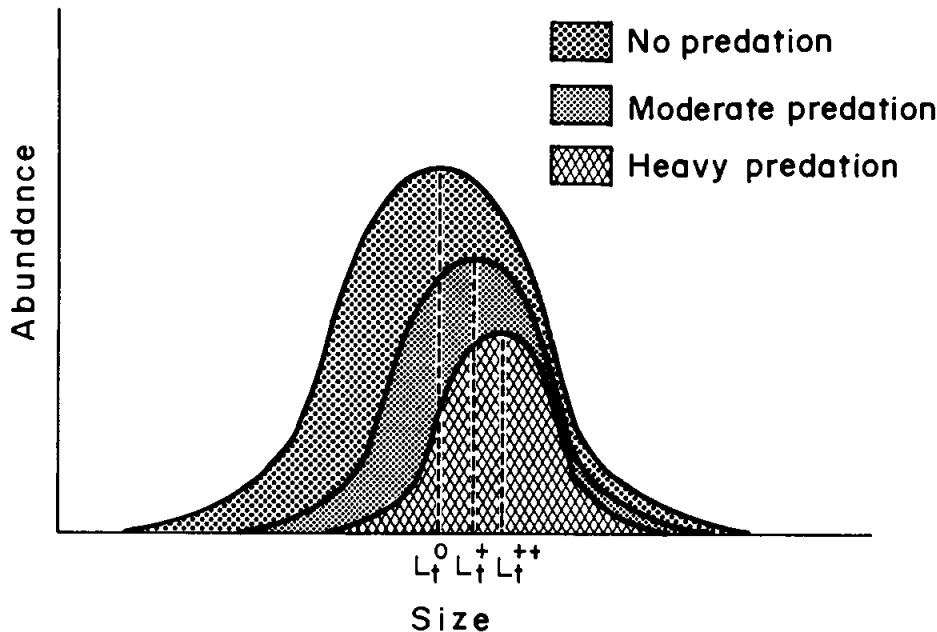

Fig. 1. Illustration of the apparent shift to larger size at age due to size-dependent predation. Where, if there had been no mortality due to predation the observed mean size at age "t" may have been L_t^0 , at a moderate level of predation it would be L_t^+ . If predation mortality is increased, the abundance at age is lowered further, the distribution is shifted toward larger sizes and the observed size at age would be L_t^{++} . The result is: $L_t^0 < L_t^+ < L_t^{++}$.

Fig. 1. Ilustración del cambio aparente a tamaños mayores en una edad debido a la predación dependiente tamaño. Donde, si no ha habido mortalidad debido a predación el tamaño promedio observado a una edad "t" puede haber sido L_t^0 , a un nivel moderado de predación este sería L_t^+ . Si la predación es incrementada, la abundancia a una edad es reducida además, la distribución es cambiada hacia mayores tamaños y el tamaño observado a esa edad sería L_t^{++} . El resultado es: $L_t^0 < L_t^+ < L_t^{++}$.

The first class is the one often considered. It has the comforting implication that, since the population would appear to be effectively eating up its food supply at high biomass, there must be substantial surplus production and associated compensatory resilience to exploitation. The second class of mechanisms also has compensatory implications, but does not imply, as does the first, that the population at high biomass may be nearing the limit of the carrying-capacity of its habitat. The third class of hypothetical mechanisms is not comforting at all, implying nothing but increased predation mortality during a population decline, i.e., a depensatory density-dependent process rather than a compensatory one.

In addressing the potential effect of school size, the relationship of vertical thickness to horizontal scale is a crucial aspect. To the extent that vertical and horizontal aspects may be functionally linked, important consequences of school size to nutrition, growth and metabolism are indicated. In fact, a general tendency toward vertically-flattened school shapes (Blaxter and Hunter 1982) may constitute an adaptation to avoid some of these consequences. Information on this functional linkage is surprisingly absent in the literature, although it would seem not difficult to acquire.

If there is a "moral" to this contribution, it illustrates the need for an "integrated ecosystem" view of marine resource population dynamics. We have seen the possibilities of three different interpretations of the same evidence, each with crucial, but highly differing, implications to stock management and preservation. To a fisheries oceanographer, the situation feels familiar. It is not very different from the dilemma faced in attempts to empirically sort out marine biological-environmental linkage mechanisms when one finds, in the typical case, that the available time series relating to various causal mechanisms are all highly intercorrelated and autocorrelated (e.g., Bakun 1987; Mendelsohn and Mendo 1987). The result is that available information is simply too limited to empirically differentiate among the possibilities.

How can we expect to make progress in sorting out the factors controlling marine resource population variability? Clearly, we need innovative approaches. And we need to recognize,

integrate and utilize information on all the various scales, both spatial and temporal, that can be accessed. For example, this contribution indicates that in addressing issues of population ecology, it is important to consider processes occurring on the scale of the school (for that matter on perhaps two school scales, both of the nighttime "feeding" school and of the daytime "resting" school), as well as on the population habitat scale. To be blunt, fisheries science needs to expand beyond the "giant guppy tank" concept of an ecosystem, and relinquish the conventional "one-spatial/temporal aggregate-data-point-per-year" approach to variability, so as to be capable of utilizing all the information in the rich patterns of variation within years, and both within and among regions (Bakun, in press). The cooperative assembly and integrative analysis of various types of data reported in this volume and in the earlier companion volume (Pauly and Tsukayama 1987) can perhaps serve as a model in this direction, both in the attempt to address variability of higher than annual frequency, despite difficulties caused by interferences related to seasonal tuning of various processes, and in its making readily available the basic data for use by anyone with an innovative idea. If the concept were to be emulated in other regional systems, the comparative method of science (Mayr 1982) might constitute a potent tool for increasing the power of empirical analysis (Bakun 1985).

Acknowledgments

Discussions with John R. Hunter, Paul E. Smith, Gary D. Sharp and Richard H. Parrish have been extremely helpful in organizing my ideas for this contribution. However, any errors of naiveté or oversimplification are certainly my own.

Abstract

A preliminary bibliography of anchoveta (*Engraulis ringens*, Jenyns 1842) (Pisces: Engraulidae) is presented, consisting of almost 500 references on its biology, ecology, and the fishery and processing industry depending on it. Much of the literature is published in English, and most of the Spanish papers include English abstracts. The major part of research which led to the publications included here was conducted in Peru. References from Chile and Ecuador have been included as far as available. An updated, computerized version of the bibliography is available as Microsoft Word or ASCII file from ICLARM at a nominal fee.

Resumen

Se presenta una bibliografía preliminar de la anchoveta (*Engraulis ringens*, Jenyns 1842) (Pisces: Engraulidae), consistente en alrededor de 500 referencias acerca de su biología, ecología y la pesquería y su procesamiento industrial dependiente de ella. La mayor parte de la bibliografía está publicada en inglés, y muchos de los trabajos en español incluyen resúmenes en inglés. La mayoría de las investigaciones que generaron los trabajos incluidos en esta publicación fueron realizadas en Perú. Referencias de Chile y Ecuador han sido incluidas en la medida que se dispuso de ellas. Una versión actualizada y computarizada de la bibliografía en archivos Microsoft Word o ASCII puede ser obtenida en ICLARM con un pago nominal.

Introduction

The anchoveta (*Engraulis ringens* Jenyns 1842) (Pisces: Clupeoidea: Engraulidae) is distributed along the west coast of South America between 4°S (northern Peru) and 42.5°S (southern central Chile) in the waters of the Humboldt Current. Being abundant in large schools, the anchoveta was heavily exploited by the world's largest single species fisheries in the late 1960s until its collapse in 1972. The fishery continues albeit on a reduced level. The catch is mainly used for the production of fish meal and oils.

The biology of the anchoveta has been investigated since the 1950s. Research on this species has been extended and intensified in the 1970s in order to understand its dependency on the South American upwelling ecosystem and its interaction with its other members, and to develop management plans for the Chilean and especially for the Peruvian anchoveta fisheries. A considerable number of papers has been written during this time, either published in the primary literature, forming a part of the "grey" (report) literature or being circulated as manuscripts.

This preliminary bibliography is an attempt to summarize the available information on the biology of anchoveta to date. Unpublished manuscripts and internal reports of IMARPE, however, have not been included. Synonyms of *Engraulis ringens* were included based on Whitehead et al. (1988). The literature search was performed in two steps, of which the first one used the following sources of information:

- (i) Aquatic Sciences and Fisheries Abstracts (ASFA) (from January 1977 to October 1988);
- (ii) Bio Sciences Information Services (BIOSIS) Previews (from January 1969 to January 1989);
- (iii) a list of publications available from IMARPE, Centro de Información y Documentación en Ciencias Acuáticas y Pesqueras, Esq. Gamarra y Gra. Valle s/n, Apartado 22, Callao, Perú;
- (iv) a bibliographic compilation on "El Niño" (Mariátegui et al. 1985);
- (v) a list of PROCOPA publications (Appendix II, this vol.)
- (vi) holdings of the ICLARM library, and
- (vii) collections of ICLARM staff, especially that of this book's senior editor.

In the second step, the available publications were accessed individually and their reference sections checked for further citations. This "snowballing" will continue during further expansion of the bibliography.

The references are numbered continuously in the bibliographic part. Numbers in brackets indicate incomplete information, e.g., with respect to page numbers. An asterisk (*) following the number indicates that the reference is part of the ICLARM library collection and/or private collections of ICLARM staff. We emphasize that the present version of this bibliography is incomplete. For example, there is limited access to the literature from Chile and the Soviet Union. As presented here, the bibliography forms the core of a computerized version, which is available as Microsoft Word or ASCII file from ICLARM at a nominal fee (see Appendix II, this vol.). This computerized version will be updated as new reprints become available and eventually will be annotated. We would be pleased to receive further information, particularly with respect to the "grey literature", i.e., unpublished reports and popular articles.

Acknowledgement

Our sincere thanks go to Dr. Daniel Pauly, ICLARM, for giving us access to his extensive collection of materials on the Peruvian anchoveta.

Abstract

An analysis of 43 maps of hake larvae (*Merluccius gayi*) distribution off the Peruvian coast, from survey areas between 3°30' and 18°S for 1966 to 1987, was performed and an index of larval abundance was calculated. This index, plotted against anchoveta biomass, showed an inverse relationship, suggesting a negative impact of anchoveta on hake eggs and larvae and on the distribution area of the hake larvae. The latter increased two- to fourfold in the period of low anchoveta biomass from 1972 to 1983. The hake larvae abundance index plotted against spawning stock biomass showed the expected positive relationship. The seasonal and interyear changes of the distribution of both larvae and adult stocks are discussed with reference to abiotic and biotic factors.

Resumen

Se efectuó un análisis de 43 mapas de distribución de larvas de merluza (*Merluccius gayi*) frente a la costa peruana, obtenidos de cruceros realizados de 3°30' hasta 18°S para el período entre 1966 y 1987 y se calculó un índice de abundancia larval. Este índice graficado contra la biomasa de la anchoveta, mostró una relación inversa, sugiriendo un impacto negativo de la anchoveta sobre los huevos y larvas de merluza y en el área de distribución de las larvas. Esta última se incrementó dos a cuatro veces durante el período de baja biomasa de la anchoveta, en los años de 1972 a 1983. El índice de abundancia de larvas graficado contra la biomasa del stock desovante indicó la relación positiva esperada. Los cambios estacionales e interanuales de la distribución de ambos, larvas y adultos, se discuten con referencia a factores bióticos y abióticos.

Introduction

The interactions in the 1970s between the major pelagic fish of the Peruvian upwelling ecosystem, i.e., anchoveta (*Engraulis ringens*), sardine (*Sardinops sagax*), mackerel (*Scomber japonicus*) and horse mackerel (*Trachurus murphyi*) on the one hand and the main demersal

*PROCPA Contribution No. 94.

species, hake (*Merluccius gayi*) on the other hand, resulted in a great abundance and area extension by the sardine and apparently also by horse mackerel and hake. This requires that we include the early life history stages of these species in our investigations of the dynamics of the Peruvian upwelling ecosystem, and that we should look for relationships between the abundance of eggs/larvae and adult biomasses.

Until some years ago, the demersal species have been neglected in discussions on interspecific relationships in the Peruvian ecosystem. Hake is the most abundant demersal species in the Peruvian coastal ecosystem. Normally, it is distributed from the Peru/Ecuador border down to 10°S. However, following the "El Niño" events of 1982-1983, the habitat of hake extended to 17°38'S (Velez and Zeballos 1983).

Previous studies on the reproduction of hake off Peru and Chile include Fischer (1959), Miranda (1966), Saetersdal and Villegas (1968), Fischer and Balbontin (1970), Balbontin and Fischer (1981), and Alheit (1986). Fig. 1 depicts hake larvae of various stages, such as discussed in this contribution.

Previous studies on hake recruitment (Wosnitza-Mendo and Espino 1986) suggested an influence of pelagic fish species, mainly anchoveta, on the early stages of hake, e.g., through predation of adult anchoveta on hake eggs (and larvae?) and interlarval (anchoveta/hake) competition. The analysis of data from 43 surveys, conducted off Peru from 1966 to 1987 provided information on hake larval abundances and on the latitudinal distribution of spawning area.

Although these surveys were not specially designed as larval survey, the data obtained allow to demonstrate some relationships between hake larvae and biomasses of hake and anchoveta.

Materials and Methods

The data used stem from 43 surveys conducted from 1966 to 1987 (Table 1), the same as used by Santander (1987) to discuss anchoveta egg distributions. Sampling was performed as described for anchoveta eggs by Santander and Sandoval de Castillo (1969) and Santander (1987), who also described the sampling gear. The surveys ranged from 10 nautical miles (n.m.) to 220 n.m. offshore and from 3°30'S to the Chilean border.

^aSee Table 3 in Santander (1987) and Pauly and Soriano (this vol.) for cross-reference to anchoveta eggs collected in these surveys.

^bMap not available.

^cMap superfluous (2 or 3 stations only).

Monthly anchoveta biomasses were taken from Pauly et al. (1987) and hake biomasses from Espino and Wosnitza-Mendo (this vol.). The relative larval abundance (No/m^2) was weighed by the latitudinal distribution area of hake larvae to provide an index of total abundance (A_L).

Results and Discussion

Hake spawn during the whole year (Fig. 2), but a major peak usually occurs in August/September (Fig. 3). In general, about 5 to 15% (in 1972 up to 25%) of the females are ready to spawn in any given month.

Table 1 suggests that the highest extension of spawning area generally occurs during the austral winter (July-September) (Santander and Sandoval de Castillo 1981). For interyear comparisons, we used only the winter cruises, during which larval abundance fluctuates between 0.28 and 10.6 larvae/ m^2 (Table 2). These numbers, weighed by the latitudinal distribution area, were plotted against anchoveta biomass. As might be seen from Fig. 4, low weighed hake larvae abundances (A_L) occur when anchoveta are very abundant.

Fig. 4. Relación entre la abundancia de larvas de merluza y la biomasa de anchoveta frente al Perú (basada en datos de Tabla 2).

This inverse relationship is mainly due to an extension of the distribution area of hake larvae. Before 1972 and after 1983, hake larvae normally did not extend to more than 8-9°S (i.e., an extension of 3 degrees). From 1972 to 1983 and in several years thereafter, hake larvae extended their distribution, in winter by 6-12 degrees), i.e., two- to fourfold (see also Santander and Sandoval de Castillo 1981).

The relation between hake larvae and hake biomass is given in Fig. 5. A stock-recruitment relationship for hake (spawning stock against two-year-old recruits) was described by Wosnitza-Mendo and Espino (1986) and Espino and Wosnitza-Mendo (1988), the latter including density-dependence (i.e., cannibalism) by means of a Ricker function. However, cannibalism on hake younger than two years does not occur, so the relationship between hake biomass and hake larval abundance continues to increase at high hake biomass levels. The values of our hake larval abundance index were estimated independently from the hake biomass estimates, which were obtained by cohort analysis, and we can exclude statistical artifacts as the cause for the

relationship in Fig. 5. Thus, the relationship between hake biomass and hake larvae is confirmed. No relationship, on the other hand, seems to exist between hake larval abundance and the number of subsequent two-year old hake recruits. Thus, between the larval stages of hake and their recruitment to the fishery two years later, mortality is determined by processes not accounted for here.

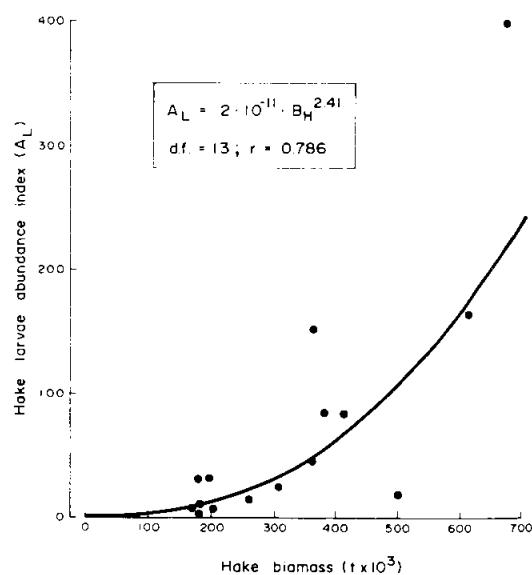

Fig. 5. Relationship between abundance of hake larvae and hake biomass off Peru (based on data in Table 2).

Fig. 5. Relación entre la abundancia de larvas y biomasa de merluza frente al Perú (basada en datos de Tabla 2).

Finally, a multiple linear regression between our hake larval abundance index (A_L), anchoveta biomass (B_A) and hake biomass (B_H) was computed, based on the data in Table 2. This resulted in:

$$\log_{10} A_L = -9.7 - 0.0681 \log_{10} B_A + 2.31 \log_{10} B_H \quad \dots 1)$$

whose slopes have the expected signs and which, with $R = 0.787$ and $d.f.=12$, is significant ($P<0.01$). The slope associated with anchoveta biomass (i.e., -0.0681) has, however, a very high standard error (0.406) suggesting that anchoveta may have no effect on the abundance of hake larvae once the (negative) correlation between anchoveta and hake biomass is accounted for.

The aim of the present study was to analyze: a) the influence of anchoveta biomass on larval hake abundance and b) the relationship between adult and larval hake.

Although statistically significant relationships were identified, the most striking result is the increment of the larval distribution area of hake from 1972 to 1983.

Espino and Wosnitza-Mendo (1988) discuss the size of adult hake distribution area as a function of environmental conditions (mainly the oxygen content of deeper water layers), which increase in austral summer and autumn and decrease in austral winter and spring. During "El Niño" events, the distribution area of hake increases extraordinarily, depending on their intensity and duration of the warm anomaly (see also Muck, this vol.).

On the other hand, hake larvae usually cover a greater area in austral winter than in summer and maintained a two- to fourfold area extension over a 12-year period (1972-1983). This is probably not caused by the range extension of adult hake; rather, it can be attributed to the drastic reduction of anchoveta biomasses which occurred in 1972, as was suggested by Santander and Sandoval de Castillo (1981).

This suggests that, for hake, winter spawning plus higher survival rate is more important than summer spawning alone. Also, the reduced biomass of anchoveta now allow hake to "rear" their larvae over a greater area with reduced predation. Figs. 6 to 15 illustrate this range extension over the period from 1966 to 1987.

Abstract

The population, in numbers and weight of hake *Merluccius gayi* off Peru, were reconstructed for the years 1953 to 1987 using J. Pope's cohort analysis. The analyses were performed with a natural mortality (M) assumed to vary with distribution area, itself varying with oceanographic conditions, especially sea surface temperature off Peru, and with a calibration based on fishery and survey data. The estimated annual biomasses of hake show an inverse relationship with those of the Peruvian anchoveta.

Resumen

Usando el análisis de cohortes de J. Pope se reconstruyó la población en número y peso de la merluza peruana (*Merluccius gayi*) en el período 1953 a 1987. Se asumió que la mortalidad natural (M) varió en función al tamaño del área de distribución, que a su vez depende de las condiciones oceanográficas especialmente la temperatura superficial del mar frente a Perú. Además se efectuó una calibración al último año con información de la pesquería y cruceros de evaluación. Las biomasas anuales halladas muestran una relación inversa con aquellas de la anchoveta peruana.

Introduction

Merluccius gayi (Guichenot), family Merluccidae, is the main hake species off the western coast of South America, where it occurs in two forms: *M. gayi peruanus* off Peru and *M. gayi gayi* off Chile (Ginsburg 1954). Off Peru, *M. gayi* is most abundant in the north where it has been commercially exploited since the mid-1960s. Earlier contributions on the distribution, biology and dynamics of *Merluccius gayi* include Solar et al. (1965), Vestnes et al. (1965a, 1965b, 1966), Stroem et al. (1966), Saetersdal and Villegas (1968), and Jones (1974).

Studies on hake have been one area of emphasis of the Instituto del Mar del Peru (IMARPE) and of the Peruvian-German Cooperative Program of Fisheries Investigation (PROCOPA), leading to a number of publications which have largely clarified the status of this resource off Peru (see Armstrong 1981; Díoses 1984; Espino et al. 1984, 1986; Espino and Wosnitza-Mendo 1984a, 1984b, 1984c, 1986, 1988; Wosnitza-Mendo et al. 1985 and references therein; Wosnitza-Mendo and Espino 1986a, 1986b).

Particularly, a positive relationship was identified between sea surface temperature (SST) and the range of hake distribution off the Peruvian coast (Espino and Urquiza 1986). This relationship, along with an associated density-dependent mechanism affecting the natural mortality (M) of younger hake (via cannibalism, see references above), was used here to reconstruct the biomasses of hake off the Peruvian coast, from 1953 to 1987, based on cohort analysis (Pope 1972) and field data collected mainly in the late 1970s and early 1980s (see Table 1).

Table 1. Basic information on Peruvian hake fishery, and on data used to run cohort analyses (see also text).

^aYears for which survey data were available for comparison with results of cohort analysis (see Fig. 1).

Since the 1980s the investigation of Peruvian hake have been oriented mainly to the implementation and application of direct evaluation models such as swept-area and analytical models such as cohort analysis (Pope 1972).

A description of the population dynamics of Peruvian hake in the years from 1971 to 1982 is presented in Espino and Wosnitza-Mendo (1986). Due to near zero catches after 1982 brought about by an El Niño and the termination of international fishing agreements, a cohort analysis up to 1986 was not possible without taking the risk of introducing a great error by selecting an

erroneous value of terminal fishing mortality (F_t) (we recall here that use of cohort analysis is only recommendable if a considerable portion of the stock is taken by the fishery (Jones 1982)). However, by integrating information from demersal research cruises on stock numbers per age group in the cohort analysis, the 1983 to 1987 segment of the biomass estimates could be determined and used for calibration (Espino and Wosnitza-Mendo 1988, Espino et al. 1988).

An analysis of hake stomach contents for the period of 1976 to 1986, in relation to its possible role as predator on anchoveta (*Engraulis ringens*) showed that, in case of coincidence of distribution area of the two species, hake could consume a considerable amount of anchoveta (Muck et al. 1988; Muck et al., this vol.). To complete the study over the 30-year period considered in the book "The Peruvian Anchoveta and Its Upwelling Ecosystem: Three Decades of Change" (Pauly and Tsukayama 1987), an effort is presented here to reconstruct hake numbers and biomasses from 1953 to 1987.

Materials and Methods

To reconstruct population numbers, the catch data presented in Table 2 were used. Between 1953 and 1964 hake fishery catches were negligible. Quarterly length-frequency distribution and age-length keys were available for the years from 1971 to 1986.

For the period from 1953 to 1970, the mean length-frequency distribution for the years between 1964 and 1970 was applied. The age-length key taken as representative of the years

a Preliminary estimate

b Underestimate

1953-1970 stems from the January 1987 survey reported in Anon. (1987), but the otoliths used for age determination stem from the earlier period. The reason for this approach was that we assumed similar stock conditions for the two periods, because both the 1953-1970 and the 1982-1986 periods experienced low exploitation rates. Thus, the structure of the population was probably similar.

The stock (in numbers) was calculated by means of a modified cohort analysis using a quarterly catch-in-number matrix. Natural mortality, formerly estimated as $M = 0.3 \text{ year}^{-1}$ (Espino and Wosnitza-Mendo 1986), was made variable depending on SST through the equation

$$M = \exp(-0.0624 + (2.0588/(1 + \exp(-0.28522(T^o - 18.16)))) \quad ...1)$$

where T^o is the mean SST in Puerto Chicama. This states that there is an inverse relationship between intensity of cannibalism and water temperature, which is also related to the changes in the size of distribution area (Espino and Wosnitza-Mendo 1988).

The cohort analysis run was initiated with a terminal population size obtained by the swept-area method (Espino and Wosnitza-Mendo 1984b; Espino et al. 1988). Thus, we avoided having to choose a terminal F which would have been very low in relation to M.

The population estimates obtained for 1981 and 1985 were verified using the population sizes estimated through the surveys. The 1971 to 1982 results from a former analysis (Espino and Wosnitza-Mendo 1986) were also used to calibrate the population estimates obtained from the cohort analysis.

In the processing of information from 1970 backwards, three different terminal F's were used for age group 10: 0.0001, 0.00025 and 0.0005 year^{-1} , since we know that the catches were very small but do not know their exact value (see Table 1).

For the comparison of the hake stock with the anchoveta population, the anchoveta biomasses were taken from Pauly et al. (1987). The relation between Peruvian hake biomass (B_M) and anchoveta biomass (B_A) was then expressed by the power function

$$B_M = a \cdot B_A^b$$

where a and b are fitted parameters.

Results and Discussion

Variation of Hake Population

Tables 2 and 3 give the estimated yearly populations (in weight and numbers, respectively) of Peruvian hake over the period considered here. Fig. 1 shows the three types of curves resulting from the three F_t values used for the 1970 to 1953 run. The values obtained for $F_t = 0.0001 \text{ year}^{-1}$ are well above those obtained for the other F_t values and do not seem realistic. In general, we would expect a more stable stock situation in the years before 1970 due to reasons presented further below. We are inclined to accept that hake biomass in the years from 1960 to 1970 varied between 2×10^5 and 3×10^5 tonnes. The years before 1960, due to the convergence of cohort estimates, do not show any differences related to the different F_t values.

We can divide the time series into three periods: the first with very low to low exploitation rates; the second, with population under full exploitation; and the third, with reoccurrence of low exploitation rates.

In the first period, from 1953 to 1972, the population does not show great fluctuations and stays at a low level, while the anchoveta biomass is at its maximum level (see Pauly et al. 1987). During this period, the high biomasses of the anchoveta might have stabilized the hake population. In its early life and up to 1 year, hake is pelagic and feeds principally on copepod larvae, copepods and euphausids (Carrasco 1986). Thus, young hakes compete for food with the anchoveta, which in the northern area (i.e., in the main distribution area of hake) also feed particularly on copepods and euphausids (A. Alamo, IMARPE, pers. comm.). The hypothesis of competition between anchoveta and hake in the early phase of the latter's life, is further

Table 3. Population of Peruvian hake (*Merluccius gayi*) in numbers $\times 10^3$ for 1953 to 1987, as reconstructed using $F_t = 0.0005 \text{ year}^{-1}$ (see text and Fig. 1).

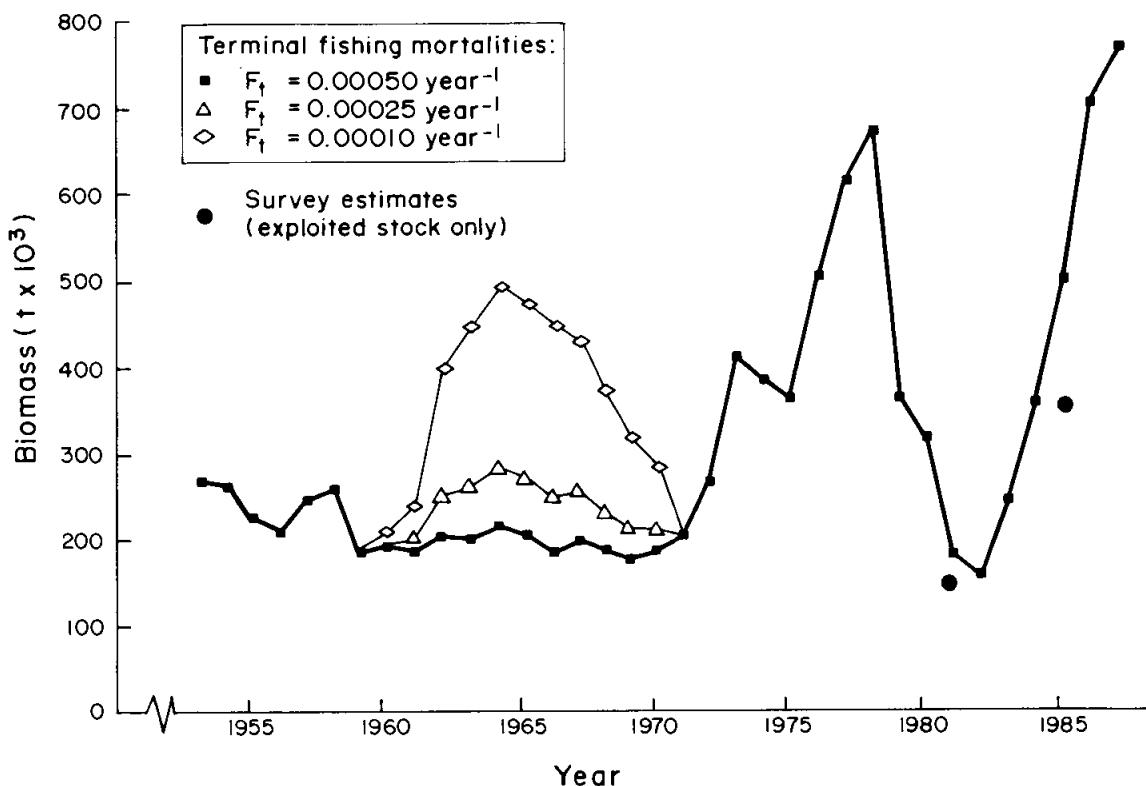

Fig. 1. Biomass of Peruvian hake *Merluccius gayi*, as reconstructed using cohort analysis and different terminal fishing mortalities for the period 1970-1980. Note closeness of survey estimates (1981 and 1985) and see Table 1 and text for details.

Fig. 1. Biomasa de la merluza peruana (*Merluccius gayi*), reconstruida usando análisis de cohortes y diferentes mortalidades por pesca terminal para el período entre 1970-1980. Notar la proximidad de los estimados de los cruceros (1981 y 1985) y ver Tabla 1 y texto para detalles.

illustrated by Fig. 2 which shows the biomass of the two-year-old hake recruits. Clearly, recruitment levels were much lower in the years before 1970, which could be explained by competition with anchoveta.

In the second period, from 1973 to 1981, the stock was fully exploited. International agreements permitted the operation of foreign high sea trawlers. Thus, we have to include the influence of fishing pressure in our considerations.

We note an increase of hake biomass in this period until 1978, with a marked decrease later on.

The biomass increase might have been due to three groups of factors, all acting simultaneously:

- A reduction of cannibalism might have taken place. Hake become cannibals at about 50 cm, i.e., at about 5 years of age (Espino and Mendieta 1978). Initially, the fishing pressure was mainly acting on older cannibalistic individuals. This will have reduced the natural mortality of young hake, and hence increased recruitment and biomass.
- As described in Wosnitza-Mendo and Espino (1986b), the "El Niño" event of 1972/73 appears to have had a positive effect on the recruitment of hake (the same occurred after the 1982/83 event). The reason for this was the increase of the potential distribution area due to higher O₂ levels near the sea bottom.
- Finally, perhaps a major factor might be, from 1972 on, the marked reduction of anchoveta biomass which stayed at a low level, and which led to a reduced consumption of hake eggs and larvae and a reduced food competition for young hakes.

The reduction of hake biomass from 1979 to 1981 is attributed to overfishing (Espino et al. 1986).

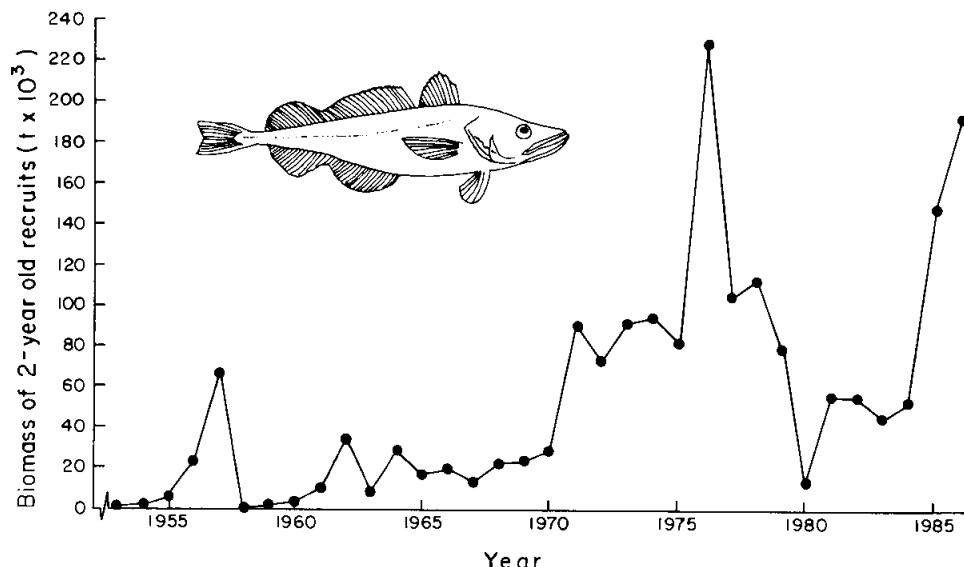

Fig. 2. Biomass of 2-year old hake *Merluccius gayi* recruits off Peru for period 1953 to 1987.

Fig. 2. Biomasa de reclutas de 2 años de la merluza peruana (*Merluccius gayi*) para el período entre 1953 y 1987.

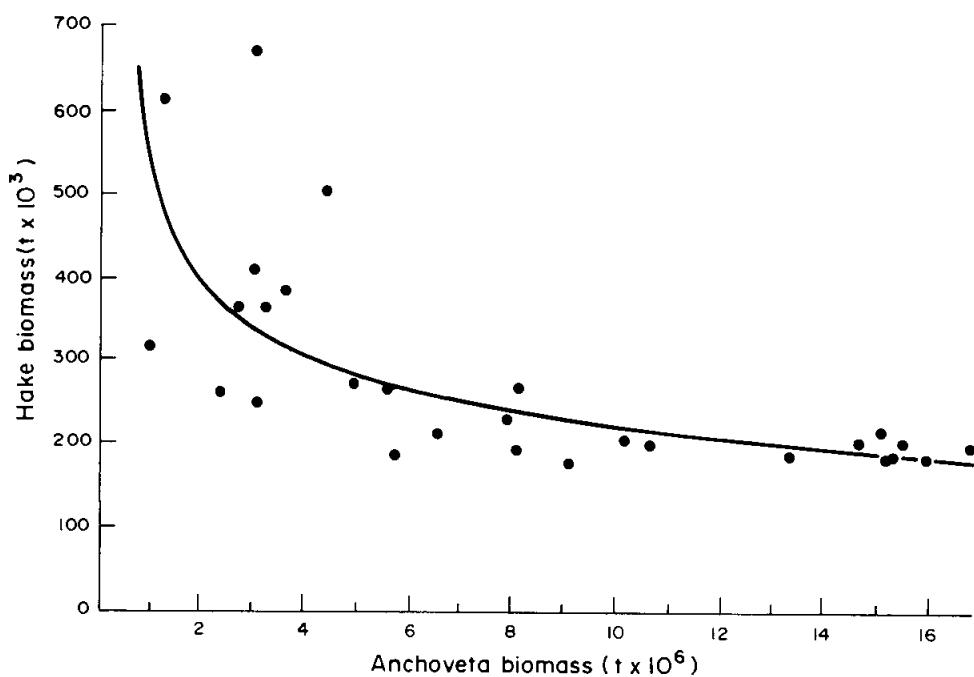

Fig. 3. Biomass of hake *Merluccius gayi* vs anchoveta *Engraulis ringens* biomasses off Peru, 1953 to 1987.
Note strong suggestion of an inverse relationship.

Fig. 3. Biomassas de la merluza (*Merluccius gayi*) versus biomasa de anchoveta (*Engraulis ringens*) frente a Perú, entre 1953 y 1987. Notar fuerte indicación de una relación inversa.

In the third period (1982-1986), the catches diminished because of two facts: first, an El Niño event dispersed the stock, rendering it inaccessible to trawling; second, the international fishing agreements ended, bringing about a reduction of the fleet.

This latter item, in combination to the recruitment-enhancing effect of "El Niño", indeed helped to prevent the stock from collapsing. In 1982, the biomass had declined to about 1.5×10^5 t, but recovered rapidly, to over 7×10^5 t ($=15$ t km $^{-2}$), a level never observed before. All of this occurred, however, in the absence of anchoveta. The preceding El Niño events of 1953, 1957/58, 1965 and 1969 did not have as strong a positive impact as the 1972/73 and 1982/83 events.

The comparison of the cohort analysis with the cruise data from 1981 and 1985 (Fig. 1) shows the same tendencies and a remarkably good fit, taking into account that the swept-area method only estimates the exploited part of the stock and underestimates the stock of younger fishes. Former cruise estimates, for the years before 1980, are highly inflated, due to the fact that the area covered by densest hake concentrations was only a small part of the total distribution area, and that most trawl hauls were made only on these densest concentrations. Furthermore, in some cruises, a catch efficiency factor of 0.25 only was used for the net.

The relationship between anchoveta and hake biomass (in tonnes) is described by the relationship

$$B_M = 6.95 \cdot 10^7 B_A^{-0.36}$$

whose linearized form has a correlation coefficient $r = 0.76$. Fig. 3 shows the original data points and the derived curve. These suggest a stock-controlling influence of anchoveta on hake, possibly via egg predation, as described in Muck et al. (1987) for sardine/anchoveta. The interactions between hake and anchoveta, however, are not unidirectional. During its early life, hake competes with anchoveta for food and might also suffer from the predation of adult anchoveta on hake eggs, especially since hake eggs, larvae and juveniles are distributed more southernly than the adults (see Sandoval et al., this vol.). On the other hand, adult hake feeds on anchoveta, but mainly in the north, where adult hakes are abundant. In any case, the impact of anchoveta on hake is probably greater than vice versa.

Abstract

A model is presented which describes the north-south distribution of hake (*Merluccius gayi*) along the coast in terms of sea surface temperature changes, themselves indicators of changes of the oxygen content in deeper water layers. This model is used, along with available information on biomass of anchoveta and hake, and on the diet of hake to estimate the overlap between the stock of anchoveta (*Engraulis ringens*) and that of hake, and the likely anchoveta consumption of hake from 1953 to the mid-1980s.

Resumen

Se presenta un modelo el cual describe la distribución norte-sur de la merluza (*Merluccius gayi*) a lo largo de la costa en relación a los cambios de la temperatura superficial del mar, indicadores también de cambios en el contenido de oxígeno en las capas profundas de aguas. Este modelo es usado con la información disponible sobre biomasa de anchoveta y merluza, y sobre la dieta de merluza para estimar el traslape entre el stock de anchoveta (*Engraulis ringens*) y el de merluza y el consumo de anchoveta por merluza desde 1953 a mediados de la década del 80.

Introduction

Mortality due to predation or caused by fishing is one of the most important processes affecting anchoveta population dynamics off Peru.

As shown for sea birds (Muck and Pauly 1987), pinnipeds (Muck and Fuentes 1987) and pelagic fishes (Pauly et al. 1987b; Muck and Sánchez 1987), the total consumption of anchoveta by various predators is (i) of the same order of magnitude as the fishery catches, and (ii) varies with the physical characteristics of the upwelling system off Peru.

With the present contribution on anchoveta consumption by semi-pelagic Peruvian hake, the "cycle" of major anchoveta predators is completed.

The Distribution Model

The size of hake distribution area is dependent of the oxygen condition in the deeper water layers (100-200 m), which shows seasonal and inter-annual variations (Espino and Urquiza 1986; Espino and Wosnitza-Mendo 1988).

*PROCOPA Contribution No. 89.

While the offshore distribution of hake is more or less constant and largely limited to the east-west extension of the continental shelf, the north-south distribution varies notably, apparently as a function of the oxygen content of the deeper water layers, which is increased when warm, oxygen-rich waters intrude, from the north, into the Peruvian upwelling ecosystem (e.g., during El Niño events).

The dynamics of the oxygen minimum zone can be expressed as a function of the mean sea surface temperature (SST), which allows the estimation of the total area of hake distribution, as described in Espino and Wosnitza-Mendo (1988).

Modifying equation (1) given by these authors, by adding as a mean offshore extension a constant "C" (=70 km), the alongshore extension of hake distribution (Ext., in km) can be approximated by:

$$\text{Ext.} = \frac{10^5}{C * (1 + e^{-0.2852 * (\text{SST}-18.16)})} \quad \dots 1)$$

During cold years, hake is most abundant in the north of Peru, within 2-7°S, with a density maximum at 5°S. This distribution pattern can be approximated by a normal distribution curve with mean (\bar{X}) = 5 and standard deviation (s.d.) = 1.25 (Fig. 1), or

$$Y = \frac{1}{\text{s.d.} * \sqrt{2\pi}} * e^{-0.5 * (\text{Lat.} - \bar{X}/\text{s.d.})^2} \quad \dots 2)$$

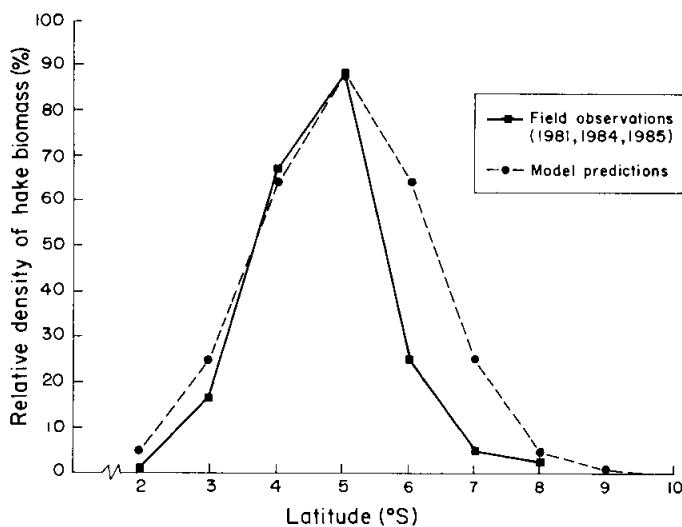

Fig. 1. Observed (in 1981, 1984 and 1985) and estimated relative density of hake biomass along the Peruvian coast.
Fig. 1. Densidad relativa estimada y observada (en 1981, 1984, 1985) de la biomasa de la merluza a lo largo de la costa peruana.

Thus, if we assume that the northern limit of hake distribution is more or less constant (i.e., 2°S, see Espino and Wosnitza-Mendo 1988), and that the southern extension of hake distribution in 1982/83 was the maximum ever, since it occurred during the very strongest El Niño on record (during which SST = 26.6°C in autumn 1983, for 4-14°S), the north-south extension estimated through equation (1) would be 1,310 km, implying a southern limit of hake distribution near 14°S (Fig. 2).

Thus, the density maximum (D_{\max} , in °S, i.e., \bar{X} in equation 2) of the latitudinal distribution of hake can be expressed as an SST-related variable:

$$D_{\max} = -0.227 + 0.309 * \text{SST} \quad \dots 3)$$

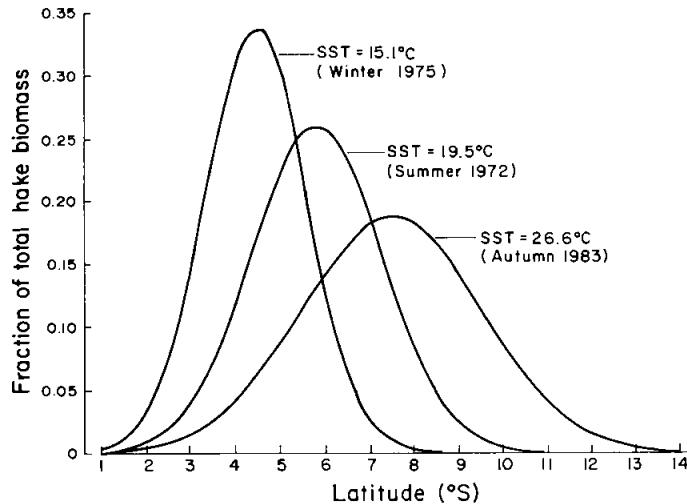

Fig. 2. Total biomass of Peruvian hake estimated to occur off 1-14°S, from three different SST regimes.

Fig. 2. Biomasa total de la merluza peruana frente a 1-14°S estimada de 3 diferentes regímenes de TSM.

and equation (2) may be rewritten as

$$Y = \frac{1}{D_{\max} * 0.25 * \sqrt{2\pi}} * e^{-0.5 * (\text{Lat.} - D_{\max})^2 / 0.25 * D_{\max}^2} \quad \dots 4)$$

Fig. 2 shows model results (equations 3 and 4) for hake density distribution under three different SST-regimes:

SST = 15.1°C (winter 1975)

SST = 19.5°C (summer 1972)

SST = 26.6°C (autumn 1983)

The percentage of total hake population (POP%) which is distributed, for a given SST, south of a given latitude, corresponds to the area under the normal distribution. This is defined, in the standardized normal distribution, by the variable Z. In this case:

$$z = (\text{Lat.} - D_{\max}) / D_{\max} * 0.25 \quad \dots 5)$$

The corresponding area (= POP%) for different values of Z are tabulated in most statistic texts and can also be calculated using

$$\text{POP\%} = \frac{1}{\sqrt{2\pi}} \int_z^{\infty} e^{-0.5v^2} dv \quad \dots 6)$$

and the polynom

$$\text{POP\%} = f(x)(b_1v + b_2v^2 + b_3v^3 + b_4v^4 + b_5v^5) * 100 \quad \dots 7)$$

where

$$f(x) = \frac{1}{\sqrt{2\pi}} e^{-0.5Z^2} \quad \dots 8)$$

and

$$v = \frac{1}{1 + 0.23164 * z} \quad ...9)$$

and where the constants

$$b_1 = 0.31938$$

$$b_2 = -0.35656$$

$$b_3 = 1.78148$$

$$b_4 = -1.82126$$

$$b_5 = 1.33027$$

(For negative values of z , the output of equation (7) is subtracted from 100.)

Table 1 gives the latitude (D_{max}) corresponding to the density maximum of hake population for different values of SST, and the percentage of the total hake population (POP%) occurring south of a given latitude.

Thus, during a warm period (e.g., SST = 23°C) $D_{max} = 6.90S$, i.e., about 26% of the total hake population is distributed south of 8°S and the subpopulation within, e.g., 8-9°S is about 15% of the total hake population (Table 2).

The data given in Table 2, together with the VPA biomass estimates of Espino and Wosnitza-Mendo (this vol.) thus allows quantification of the hake biomass within each degree of latitude along the coast of Peru in relation to SST.

The Feeding Model

The total daily food intake of a population ($R_{tot.}$) can be expressed as the sum of the intake by each age (or weight) group (R_t):

$$R_{tot} = \sum_{t=n}^{t_{max}} N_t * R_t \quad ...10)$$

where N_t is the number of individuals of age t and R_t the mean daily ration of an individual of age t .

The daily anchoveta consumption (R_a) can be expressed as a fraction of total consumption by:

$$R_a \sum_{t=n}^{t_{max}} = R_t * A \quad ...11)$$

where $A (>0, <1)$ quantifies the availability of anchoveta to the predator. This availability can be viewed as a function of the biomass and the vulnerability of anchoveta (Muck and Pauly 1987); Muck and Fuentes 1987; Muck and Sanchez 1987).

Stomach content analyses show that anchoveta availability to hake depends on predator size and varies between different areas off the Peruvian coast (Muck et al. 1988; Fuentes et al., in press). Fig. 3 shows annual means of the fraction of anchoveta (P%-anch.) in the stomach contents of adult hake (35-45 cm) for the period 1975-1986.

Table 1. Percentage of total hake population south of a given latitude along the Peruvian coast, as related to SST.

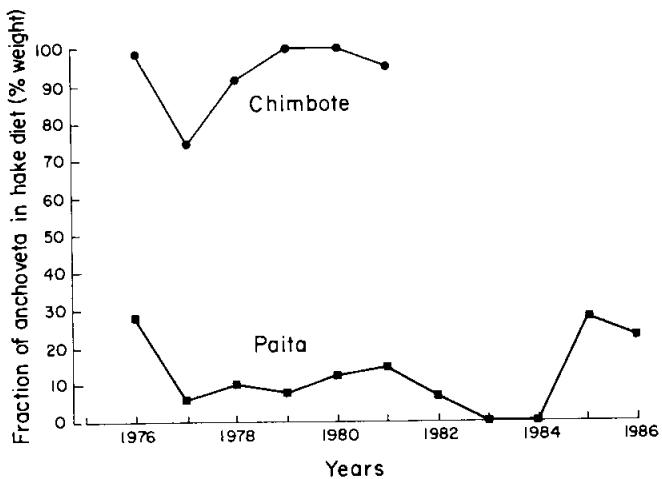

Fig. 3. Fraction of anchoveta (weight %) in stomach contents of Peruvian hake from 1976-1981 off Chimbote, and from 1976 to 1986 off Paita.

Fig. 3. Fracción de anchoveta (% peso) en el contenido estomacal de la merluza peruana desde 1976-1981 frente a Chimbote y de 1976-1986 frente a Paita.

While in the Paita area ($4-6^{\circ}\text{S}$) in 1976-1981, anchoveta represented only ca. 10% of total stomach contents, this value was much higher (i.e., over 90%), during the same period, off Chimbote ($8-10^{\circ}\text{S}$).

The values of $\text{P\%}-\text{anch.}$, for hake of 35 to 45 cm caught off Paita were significantly ($r = 0.79$, d.f. 9; $P < 0.05$) positively correlated with mean annual anchoveta biomass or B_a (see also Muck, this vol., i.e.)

$$\text{P\%}-\text{anch.} = 2.03 + 5.398 * B_a \quad \dots 12)$$

or, when excluding the years with less reliable anchoveta biomass estimates (i.e., 1980 to 1983)

$$\text{P\%}-\text{anch.} = -1.67 + 5.398 * B_a \quad \dots 13)$$

($r = 0.86$, d.f. = 5; $P < 0.05$.) Thus, increasing anchoveta total abundance within $4-14^{\circ}\text{S}$ results, in the Paita area, in an increasing anchoveta component in hake stomachs. (The same can be observed for hake caught off Chimbote during the period 1976-1978.)

Eliminating the intercept of equation (13) by forcing the line through the origin leads to

$$\text{P\%}-\text{anch.} (\text{Paita}) = 4.98 * B_a \quad \dots 14)$$

Thus, the total anchoveta biomass estimated for the area $4-14^{\circ}\text{S}$ (Pauly et al. 1987a) must be close to or beyond $20 \text{ t} \times 10^6$ for the anchoveta fraction to reach 100% in the stomachs of hake of 35-45 cm, in the area of Paita.

On the other hand, in the area of Chimbote, $\text{P\%}-\text{anch.}$ values close to 100 have been found, for hake of 35-45 cm, during 1976, 1978, 1979 and 1981, when mean total anchoveta biomass was only of about $3.2 \text{ t} \times 10^6$. This can be expressed as:

$$\text{P\%}-\text{anch.} (\text{Chimbote}) = 30.9 * B_a \quad \dots 15)$$

Interpolating between Paita (5°S) and Chimbote (9°S) equations (4) and (15) can now be combined to:

$$\text{P\%}-\text{anch.} = (-27.42 + 6.48 * \text{Lat.}) * B_a \quad \dots 16)$$

which quantifies the anchoveta fraction in the stomachs of hake ranging from 35-45 cm as a function of (i) anchoveta biomass and (ii) latitude south.

Multiplying equation (16) by 0.01, we obtain the anchoveta availability index (A) of equation (11):

$$A = ((-27.42 + 6.48 * \text{Lat.}) * B_a) * 0.01 \quad ...17)$$

(In all computations, when equation (17) produced estimates of A larger than unity, A was set equal to 1.)

Fig. 4 shows the dynamics of anchoveta availability to hake for different values of anchoveta total biomass, and suggests that the north-east gradient between Paita and Chimbote is eliminated when anchoveta total biomass is higher than about 10×10^6 tonnes.

To generalize equation (16) for size groups of hake other than 35-45 cm, the data of Table 3 have been used (see also Fig. 5).

The increase of anchoveta in the diet of hake between 22 and 42 cm reflects the shift of these fish from a pure zooplankton diet to a fish diet, while the decreasing trend of anchoveta in the diet of hake > 42 cm is related to their transition from a diet of small fishes (i.e., anchoveta) to larger ones (sardine, hake).

Fig. 6 shows the size related changes in preferred prey item for the area of Paita. This figure suggests that hake below 20 cm and above 70 cm do not feed on anchoveta. Fig. 7 shows the size-frequency distribution of anchoveta in the stomachs of hake of 20-70 cm.

The VPA-estimates of hake biomass in Espino and Wosnitza-Mendo (this vol.) refer to age group while the stomach content analyses data refer to size groups (of 5 cm width).

To convert size to age, the inverse of the von Bertalanffy formula was used:

$$t = t_0 - 1/K * \ln (1 - L_t/L_\infty) \quad ...18)$$

The constants for hake are (Dioses 1985):

$$K = 0.139 \text{ year}^{-1}$$

$$L_\infty = 99 \text{ cm}$$

$$t_0 = -0.278 \text{ year}$$

The results of the length/age conversion are shown in Table 3 along with P% anch. values put on an age basis. The frequency distribution of the latter can be approximated by:

$$Y = e^{-0.5} * \left[\frac{t + 0.5 - 1.5}{0.4} \right]^2 \quad ...19)$$

where "t" refers to hake age groups 1-7, i.e., to those age groups which feed on anchoveta. Thus, we can generalize equation (17) to:

$$A = ((-27.42 + 6.48 * \text{Lat.}) * B_A) * e^{-0.5} * \left[\frac{t + 0.5 - 1.5}{0.4} \right]^2 * 0.01 \quad ...20)$$

which allows the estimation of anchoveta availability for each age group of hake as a function of anchoveta biomass and latitude south.

The total daily ration of an individual of the age group t (R_t) can be estimated using the mean total stomach weight per age group (STW_t) as suggested in Durbin et al. (1983):

$$R_t = STW_t * a * e^{(b * \text{temp.})} * 24 \quad ...21)$$

Table 3. Summary of analyses of hake stomach content for the area off Paita, 1976-1986.^a
 Tabla 3. Resumen del análisis del contenido estomacal de la merluza en el área de Paita, 1976-1986.

| Total Length (cm) | Age class (years) | Age group used for VPA | Weight of total stomach content | | | Fish weight in total stomach contents (%) | (%) | (s.d.) | (rel.) |

| > 65 - 70 | > 7.3 - 8.5 | | | | | | | | |

^aThese results take account of empty stomachs (47.1% of total).

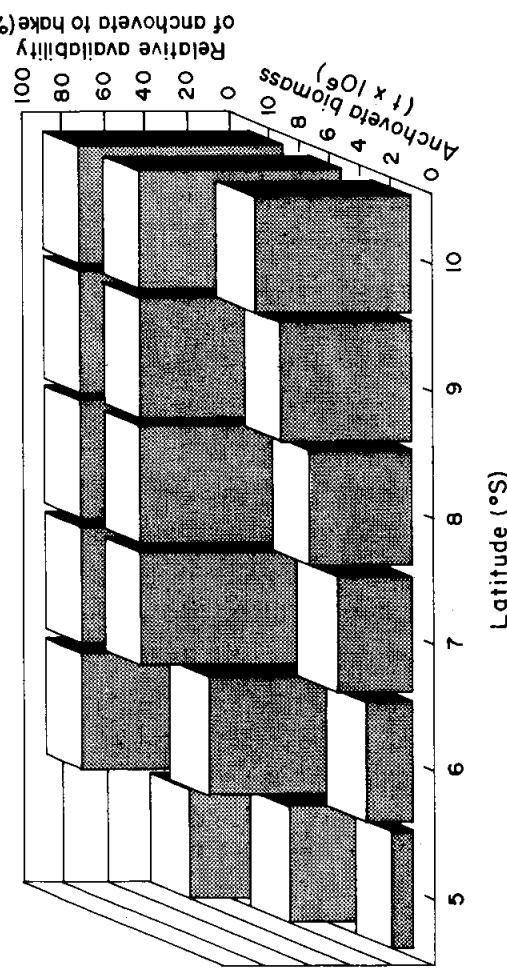

Fig. 4. Relative availability of anchoveta to Peruvian hake as a function of anchoveta biomass and latitude (5-10°S).
 Fig. 4. Disponibilidad relativa de anchoveta para la merluza peruana como una función de la biomasa de anchoveta y la latitud (5-10°S).

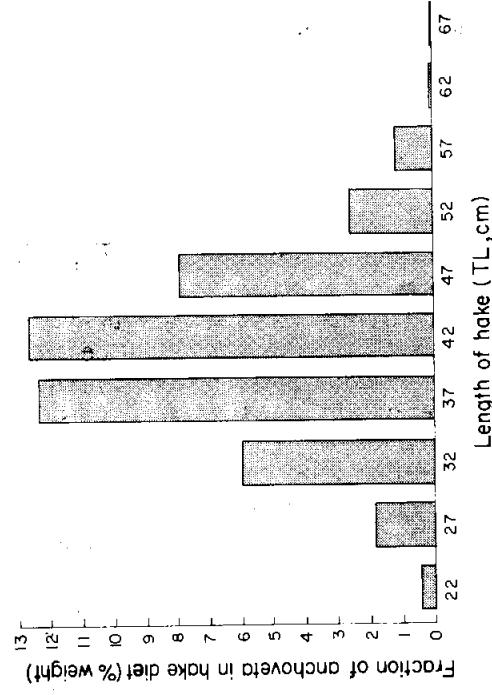

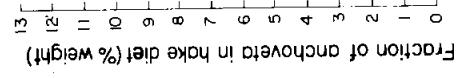

Fig. 5. Weight fraction of anchoveta in the diet of Peruvian hake of 22 to 67 cm total length.
 Fig. 5. Fracción del peso de la anchoveta en la dieta de la merluza peruana de 22 a 67 cm de longitud total.

where "a" and "b" are constants relating food type and environmental temperature (temp.) to gastric evacuation rate.

As proposed in Durbin et al. (1983), "a" should vary, when R_t is expressed in per fish per day, from 0.04 (for non-fish food) to 0.004 (for fish food). The value of "b" was set here at 0.111, while "temp." was set at a constant value of 14.5°C, pertaining to the deeper layers of the Peruvian upwelling system.

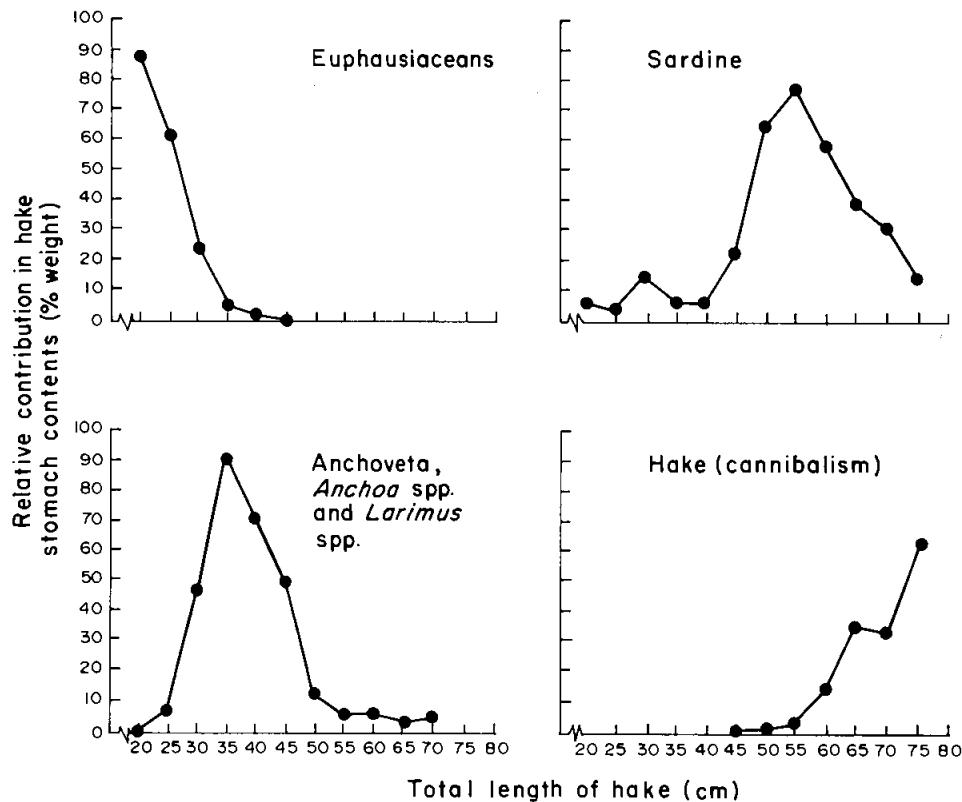

Fig. 6. Relationship between hake size and the proportion of various preferred prey items in their stomachs (based on samples collected off Paita, Peru).

Fig. 6. Relación entre el tamaño de la merluza y la proporción de varios ítems de presas preferidas en sus estómagos (basadas en muestras colectadas de Paita, Perú).

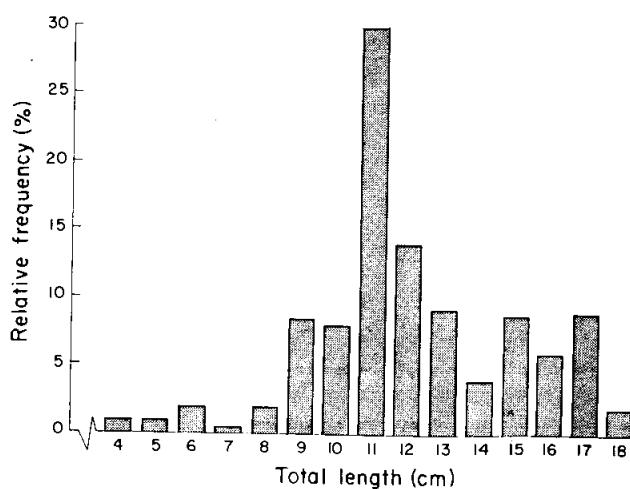

Fig. 7. Size composition of anchoveta in the stomach of Peruvian hake of 20-70 cm.

Fig. 7. Composición por tallas de la anchoveta en el estómago de la merluza peruana de 20-70 cm.

As shown in Fig. 6 the percentage of fish in hake stomach is related to predator size. Recalculating the data given in Fig. 6 and converting hake size to age (Table 3) suggest that the change from zooplankton diet to an almost pure fish diet occurs during the first 3 years (Fig. 8). This can be approximated by:

$$\% \text{ fish in hake diet} = \frac{95}{1 + e^{(5 - 2.5 * t)}} \quad ...22)$$

Similarly, the term "a" of equation (21) can be made to vary from 0.004 (for hake age groups feeding on fish) to 0.04 (for hake age groups feeding on zooplankton) using:

$$a_t = \frac{0.33}{\left[\frac{95}{1 + e^{(5 - 2.5 * t)}} \right]} \quad ...23)$$

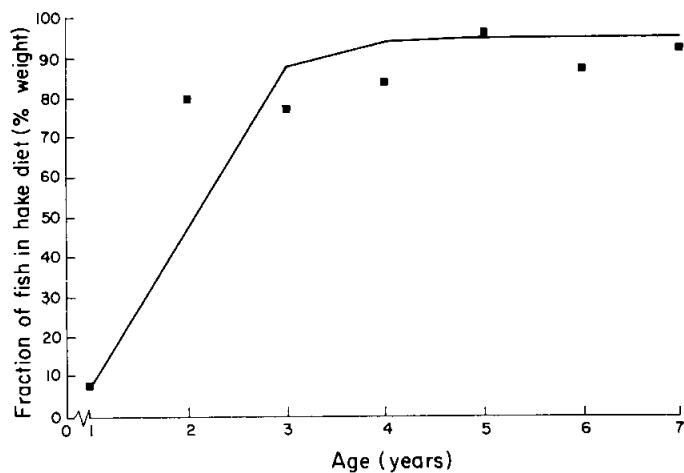

Fig. 8. Relationship between the age of Peruvian hake and the fraction of fish in their diet.

Fig. 8. Relación entre la edad de la merluza peruana y la fracción de peces en su dieta.

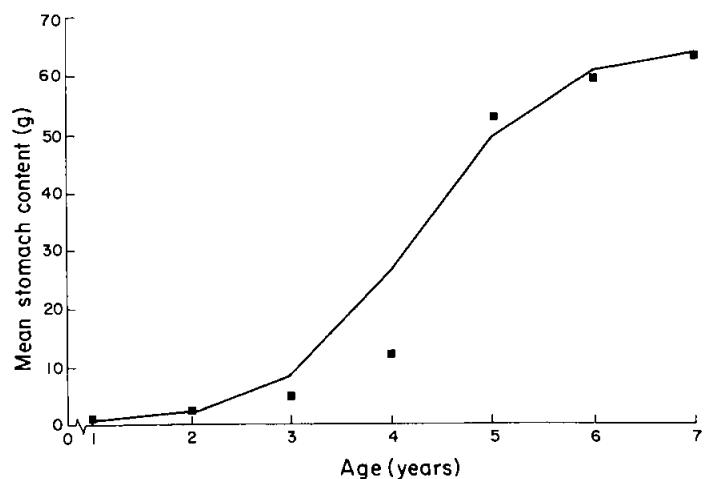

Fig. 9. Relationship between mean stomach content weight and age of Peruvian hake.

Fig. 9. Relación entre el peso promedio del contenido del estómago y la edad de la merluza peruana.

The mean stomach content weight (in g wet weight) of individual hake increases with hake age (or size, see Table 3 and Fig. 9), i.e.,

$$STW_t = \frac{65}{1 + e^{0.77(8.5 - 2t)}} \quad ...24)$$

Thus, the complete equation for calculating the daily anchoveta consumption (in tonnes/day) by the hake population (i.e., by age group 1-7) within 4-14°S for different SST regimes and anchoveta biomasses (B_a , in millions of tonnes) is

$$\begin{aligned} \text{daily anchoveta consumption by hake population} &= \sum_{\text{lat. } = 4}^{\text{lat. } = 14} \sum_{t=1}^{t=7} N_{t1 \text{ lat.}} * \frac{65}{1 + e^{0.77(8.5 - 2t)}} \\ &\quad * \frac{1/95}{1 + e^{(5 - 2.5t)}} * 0.33 * 24 \\ &\quad * e^{0.111 * 14.5} * (-27.4 + 6.48 * \text{lat.}) \\ &\quad * B_a * e^{-0.5 \left(\frac{t * 0.05 - 1.5}{0.4} \right)^2} * 0.01 \quad ...25) \end{aligned}$$

Results and Discussion

The estimates of anchoveta consumption by Peruvian hake within 4-14°S are given on a monthly basis in Table 4 and on an annual basis in Fig. 10. These estimates may be used to assess the impact of hake on the natural mortality of anchoveta (see Pauly and Palomares, this vol.).

^aThe estimates derived from equation (25) were originally expressed on a seasonal basis (e.g. southern spring = Jan. + Feb. + March) and have been put on monthly basis through linear interpolations between the central months of each season (i.e., February, May, July, November).

Anchoveta consumption of hake varied on a seasonal basis between 200,000 t (summer 1978) and 900 t (winter 1954) and on an annual basis between 370,000 t (1978) and 5,240 t (1954) (Fig. 10).

The variation in estimated anchoveta consumption depends on changes in (i) abundance of fish-feeding hake age groups, (ii) the north-south extension of hake distribution area and (iii) anchoveta availability for hake.

For age group abundance, the VPA-estimates of Espino and Wosnitza-Mendo (this vol.) has been used. These authors found an inverse relationship between anchoveta biomass and hake biomass and suggest that anchoveta controls hake population growth at the level of egg and larvae predation. This hypothesis is supported by time series analysis of hake larvae abundance (Sandoval et al., this vol.), and agrees with the findings of Muck et al. (1988) for sardine in that anchoveta controls population growth of other fish species by feeding on their eggs and larvae.

Hake distribution has been modeled as a function of SST, which reflects the seasonal and El Niño-related dynamics of the size of the oxygen minimum zone depths 100-200 m (Espino and Wosnitza-Mendo 1988). These dynamics are as follows: increasing sea surface temperature results in a southward hake population expansion, invading the main anchoveta distribution area (4-14°S.L.). Thus, anchoveta consumption of hake during summer (January-March) has been estimated 2-3 fold higher than during winter (July-September), when the overlap between predator and prey distribution areas is less pronounced.

These effects become more evident during El Niño events, when hake, usually distributed within 3-7°S, moves southward. The data of Fuentes et al. (in press) for Callao (12°S.L.) and Pisco (13.5°S.L.) show that when such conditions prevail, hake feed predominantly on anchoveta.

Anchoveta availability for hake is a positive function of anchoveta biomass and hake size. The model includes an anchoveta distribution component which results in an increasing availability of anchoveta to hake, in the area 4-7°S (= northern boundary of anchoveta distribution) with increasing anchoveta total biomass.

The modeling of SST, i.e., oxygen-related changes in north-south hake distribution was performed on the basis of a normal distribution whose parameters (mean, standard deviation) were empirically derived from survey data.

The model results in a latitudinal shift of the density maximum of hake distribution as a function of SST, accompanied by north-south expansion or contraction, respectively, of the (potential) hake distribution area. Thus hake is more concentrated during cold periods than during warm ones, which is bound to affect cannibalism and prerecruit survival, as suggested in Espino and Wosnitza-Mendo (this vol.).

With the estimation of anchoveta consumption by the Peruvian hake, the "cycle" of the most important anchoveta predators has been completed. When comparing mean anchoveta consumption by hake with the mean consumption by other anchoveta predators, fishery included, (Muck et al. 1988) for the period 1953-1987, hake occupies the penultimate position.

Similar to mackerel and horse mackerel, hake belongs to the group of opportunistic predators whose importance for anchoveta mortality varies with the dynamics of oceanographic conditions: changes in sea temperature (mackerel, horse mackerel) and oxygen conditions (hake) affect the distribution area of these species, resulting in a variable predation stress on anchoveta, which is higher in summer than during winter and very high during El Niño events.

Acknowledgements

The author wishes to thank Dr. C. Wosnitza-Mendo and Mr. M. Espino for the VPA-estimates of hake abundance used here, Mr. H. Fuentes and Mrs. E. Antonietti for the data reproduced here as Fig. 6, and Ms. A. Zafra de Moreno and C. Estrella for their assistance with data processing.

Abstract

The horse mackerel fishery of the South Pacific currently dominates the world's catch of horse mackerels. The rapid increases in catches of horse mackerel by South American purse seine fleets and the distant water USSR trawl fleet are discussed and the geographical expansion of the trawl fishery is shown utilizing ship surface weather observations.

Due to disagreement on the taxonomic identity of the species which supports the fishery, a review of the world's *Trachurus* was made. The results of this review show that neither of the eastern Pacific forms of *Trachurus* merits full species rank. It is concluded that both are subspecies of the oceanic horse mackerel (*Trachurus picturatus*); *T.p. symmetricus* in the northeastern Pacific and *T.p. murphyi* in the southeastern Pacific. It is further suggested that it is likely that the range of *T.p. murphyi* extends clear across the southern hemisphere west wind drift region (i.e., from the South Atlantic to Chile).

Resumen

Las pesquerías de jurel en el Pacífico Sur dominan actualmente las capturas mundiales de jureles. Se discute el rápido incremento en las capturas de jurel por las flotas cerqueras sudamericanas y la flota arrastrera soviética que opera en aguas distantes y se muestra la expansión geográfica de las pesquerías de arrastre mediante el empleo de observaciones del clima efectuadas por los barcos.

Se hace una revisión de los *Trachurus* del mundo, en vista de los desacuerdos en la identidad taxonómica de las especies que soportan las pesquerías. Los resultados de esta revisión muestran que ninguna de las formas de *Trachurus* del Pacífico Oriental amerita plenamente la jerarquía de especie. Se concluye que ambas son subespecies del jurel oceánico (*Trachurus picturatus*); *T.p. symmetricus* en el Pacífico Nororiental y *T.p. murphyi* en el Pacífico Suroriental. Se sugiere además que es probable que el rango de *T.p. murphyi* se extienda a través de la región con vientos del oeste del hemisferio sur (desde el Atlántico Sur a Chile).

Introduction

Horse mackerels, of the genus *Trachurus*, are a widespread group occurring in nearly all of the temperate and subtropical, neritic regions of the oceans and they have extensive, but poorly understood, oceanic distributions in several regions. They also occur in a number of tropical neritic regions. The taxonomy of the group is in considerable flux and their extensive distribution is undoubtedly, at least partially, the cause of the present taxonomic confusion: forms which are very similar in morphology and meristics, but widely separated geographically, are assumed, *a priori*, to be separate species by many workers.

Over the last two decades the horse mackerels have had one of the largest increases in the world's fish catch. Landings rose from 1.2×10^6 tonnes (t) in 1965 to 3.9×10^6 t in 1984. In 1965 catches of horse mackerel were principally from the northern hemisphere (0.80×10^6 t); however, the increase in catches has been entirely the result of developing fisheries in the

southern hemisphere (Fig. 1A). Although horse mackerel occur in much of the world ocean, the bulk of its catches, and supposedly biomass, is concentrated in the eastern boundary currents (Fig. 1B).

Regionally the catches of horse mackerels have exhibited tremendous changes over the last two decades (Table 1). In 1965 half of the world catch of *Trachurus* came from the northwestern Pacific (0.55×10^6 t) and the rest was primarily taken in the northeastern Atlantic (0.22×10^6 t) and southeastern Atlantic (0.31×10^6 t). By the early 1970s catches from the northwestern Pacific had declined greatly, whereas catches from the other two regions had significant increases. Catches reached a maximum of 0.91×10^6 t in the northeastern Atlantic in 1973 and a maximum of 0.97×10^6 t in the southeastern Atlantic in 1978. Most of these increases in catches were due to the development of distant-water trawl fisheries off North and South Africa by European nations.

Development of the South Pacific Fishery

The most significant change in the world's horse mackerel catches occurred as the result of the development of the southeastern Pacific fishery which rose from 0.015×10^6 t in 1965 to a maximum of 2.32×10^6 t in 1984 (Fig. 1C). The South Pacific fishery was developed in the early 1970s by Chilean purse seiners forced to alter their fishing strategies due to the collapse of the

anchoveta fishery in 1972-1973 (Table 2). Chilean landings of horse mackerel reached 0.5×10^6 t in 1978 and, except for the El Niño year of 1983, have exceeded 1.4×10^6 t since 1981. In the early 1970s Peru also began to develop a purse seine horse mackerel fishery; however, this fishery has not achieved the production of the Chilean fishery and with the exception of 1977-1978, when landings were near 0.5×10^6 t, landings have averaged less than 0.1×10^6 t.

Both the Chilean and Peruvian horse mackerel fisheries are neritic fisheries with catches almost exclusively coming from their respective 200 mile economic zones. The Chilean fishery started in northern Chile, in the Arica-Antofagasta region and expanded to central Chile in the late 1970s (Serra 1987). During the 1980s the Chilean landings have been about equally divided between the Arica-Antofagasta region ($18-24^\circ S$) and the Talcahuano region ($37^\circ S$); landings in the Coquimbo region of central Chile ($30^\circ S$) have been an order of magnitude less than in the other two regions (Serra 1987). Fishing areas for the Peruvian catches are not well-documented in the available literature.

In 1978, trawlers from the USSR began fishing for horse mackerel offshore of the 200 mile limits of Peru and Chile and during the period 1979-1985 they have annually taken between 0.49 and 0.59×10^6 t in the offshore area (Table 1). The development and distribution of this distant water trawl fishery is well documented in the positions of the trawlers as reported in international meteorological observations. At the beginning of the fishery (1979) the reported positions were spread out in a band along the coast, outside of the 200 mile zones (i.e., between 80°W and 90°W from 10°S to 45°S in Fig. 2A). By 1983 reports show the fishery was concentrated off southern Chile at about 80°W and 40°S (Fig. 2B); however, there were also a considerable number of reports along 85°W north of the area of concentration. There was an absence of reports within Chile's 200 mile zone; Chile also has 200 mile zones around San Felix Island and Juan Fernandez Archipelago. By 1985, in addition to a distribution of reports similar to 1983, the reports show that the fishery extended westward along the west wind drift between 39 and 45°S (Fig. 2C).

To evaluate the seasonality of the Soviet trawl fishery, the meteorological reports were limited to Soviet vessels and to 1984-1987, the period when the fishery was operating in the offshore west wind drift region. During the austral spring (October-December) the meteorological reports are furthest to the north with reports concentrated between 34-41°S and 78-92°W (Fig. 3A). Reports are noticeably absent in the 200 mile zones around San Felix Island (26°S, 80°W) and the Juan Fernandez Archipelago (33°S, 80°W) but there are reports in international waters between the two zones and between the San Felix Island 200 mile zone and the continental 200 mile zone. During the austral autumn (April-June) the reports are concentrated in two regions

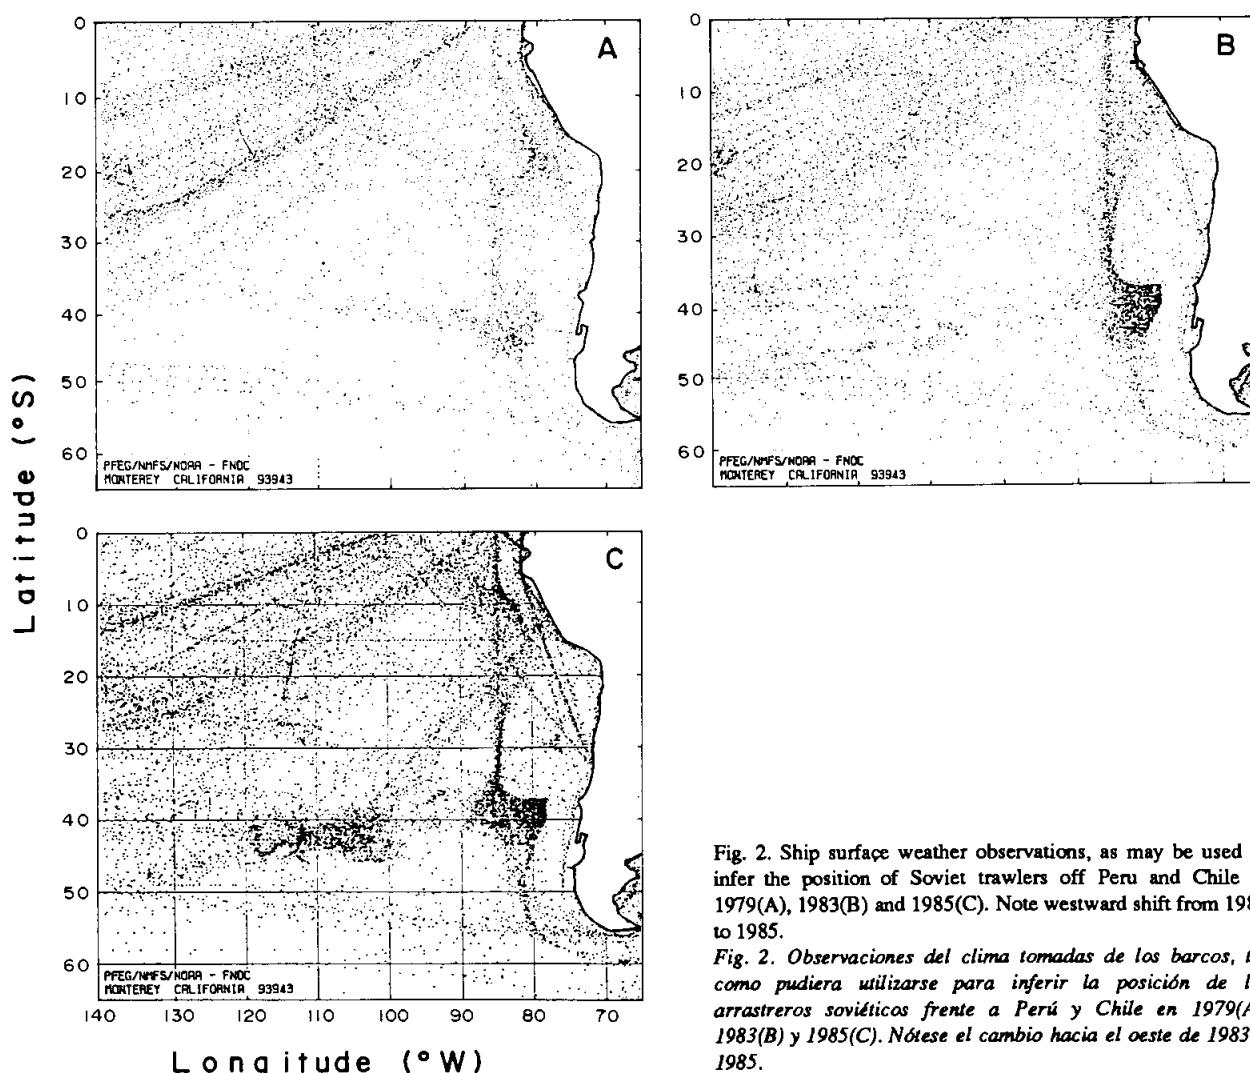

Fig. 2. Ship surface weather observations, as may be used to infer the position of Soviet trawlers off Peru and Chile in 1979(A), 1983(B) and 1985(C). Note westward shift from 1983 to 1985.

Fig. 2. Observaciones del clima tomadas de los barcos, tal como pudiera utilizarse para inferir la posición de los arrastreros soviéticos frente a Perú y Chile en 1979(A), 1983(B) y 1985(C). Nótense el cambio hacia el oeste de 1983 a 1985.

(Fig. 3B). The first is about five degrees south of the spring concentration (i.e., between 39-45°S and 79-90°W) and the second is much further offshore (39-45°S and 100-120°W). In both spring and autumn there are also considerable numbers of reports in the offshore region extending toward New Zealand.

The South Pacific distribution of the meteorological reports from the Soviet trawl fleet suggests that, in the offshore region, horse mackerel are concentrated along the South Pacific subtropical convergence and that they seasonally move north and south with the convergence. It appears that the horse mackerel are able to complete their entire life cycle in the South Pacific subtropical convergence; independent of the neritic zone. Evseenko (1987) reported several larvae and a juvenile in the South Pacific convergence and Bailey (1989) shows that the horse mackerel spawns across the South Pacific from New Zealand to Chile. Bailey found juvenile horse mackerel along the subtropical convergence from 128°W to 166°W.

Review of the Taxonomy of *Trachurus*

As shown above, the recent increase in the world's catch of *Trachurus* is primarily due to increases in the catch off Pacific South America. The FAO catch statistics consider the horse mackerel in this region to be *Trachurus murphyi*, but there is little agreement in the literature as to the correct species name. For example, in Peru the commonly used name is *T. symmetricus murphyi*, whereas in Chile the name *T. murphyi* is used (Santander and Flores 1983; Serra 1983). Therefore a review of the literature on the taxonomy of the horse mackerels was carried out to ascertain the status of the Pacific South American form.

The world's trachurids have been reviewed by Nichols (1920, 1940), Berry and Cohen (1974) and Shaboneyev (1980). Since Nichols (1920) the literature has contained 17 species and 2 subspecies (Table 3). The number and relative size of the scutes along the lateral line and the relative length of the dorsal accessory lateral line has been of primary importance in separating the various forms of *Trachurus* and all three reviews are heavily based on these characteristics. The taxonomy of the group is still in flux and it is not known if the forms in many regions are separate at the species, subspecies or even lower levels. The problem was perhaps best stated by Nichols (1940):

"The systematic treatment of the forms of *Trachurus* is puzzling. They are sometimes so nearly identical from different oceans that authors synonymize them, but in no case where I have had material for comparison do they seem to me to be quite identical. They might all be races of a single widely distributed species except that two quite unlike forms are often recognized in the same waters."

Nichols (1940) recognized 12 species but he concluded by suggesting that the genus might be divided into 3 species, each having a number of geographically isolated races. Under this arrangement all of the species described to that time would have been races of *T. trachurus*, *T. picturatus* and *T. mediterraneus* (Table 4).

Table 3. Original descriptions of *Trachurus* used in recent literature.

Berry and Cohen (1974) synonymized two of the species recognized by Nichols (1940), accepted two new species described by other authors and described a new species; thus recognizing 13 species. They did not group the species as did Nichols but described the relationships between similar forms in different regions. These descriptions result in groups of similar species which are very much like those of Nichols (Table 4). They also showed that there is only one species in the entire western Atlantic (*T. lathami*) and this has recently been verified by Saccardo (1987).

^aNumber of scutes as given in Shaboneyev (1980).

^bNumber of scutes as given by other authors.

^c Depth of the largest scute in the posterior part of the lateral line as a percentage of head length as given in Shaboneyev (1980).

^dBerry and Cohen (1974) made no comment on the relationships of these forms.

Shaboneyev (1980) accepted 11 species of *Trachurus*. He followed Nekrasov (1978) and Komppowski (1975) treating *capensis* as a subspecies of *T. trachurus* and he also followed Kotlyar (1976) and Shaboneyev and Kotlyar (1979) in considering *murphyi* to be a subspecies of *T. symmetricus*. Shaboneyev placed the 11 species into three groups of similar species and one aberrant form (Table 4).

The grouping of similar forms by Nichols (1940), Berry and Cohen (1974) and Shaboneyev (1980) are nearly identical and result in a separation of *Trachurus* into a temperate form (the *trachurus* type), a tropical form (the *mediterraneus* type) and an oceanic form (the *picturatus* type). The geographical distributions of Shaboneyev's *trachurus* group (Fig. 4A) and *mediterraneus* group (Fig. 4B) demonstrate the separation into a more temperate group (*trachurus*) and a more tropical group (*mediterraneus*).

The number of scutes is considerably greater in the oceanic form than the other forms (Table 4) and all three reviews are in agreement in the species included in this group; however, there are minor differences in the inclusion of *japonicus* and *novaehollandia* within the other two groups. These are the two forms which Nichols (1940) was unsure of, stating that *muccullochi* (now *novaehollandia*) should perhaps be included in the *trachurus* group and that *japonicus* should perhaps be included in the *mediterraneus* group. Berry and Cohen (1974) stated that *muccullochi* may be a southern hemisphere cognate of *japonicus* and that *japonicus* was the most morphologically similar to *lathami* and they placed both *muccullochi* and *japonicus* in the *mediterraneus* group. Shaboneyev (1980) separates the various forms in his *trachurus* and *mediterraneus* groups primarily on the relative size of their scutes. In his *trachurus* group the depth of the largest scute in the posterior part of the lateral line averages from 12.2 to 16.6% of the head length; whereas in his *mediterraneus* group it averages from 22.5 to 26.4% (Table 4). He therefore placed both *novaehollandia* (= *muccullochi*) and *japonicus* in his *trachurus* group.

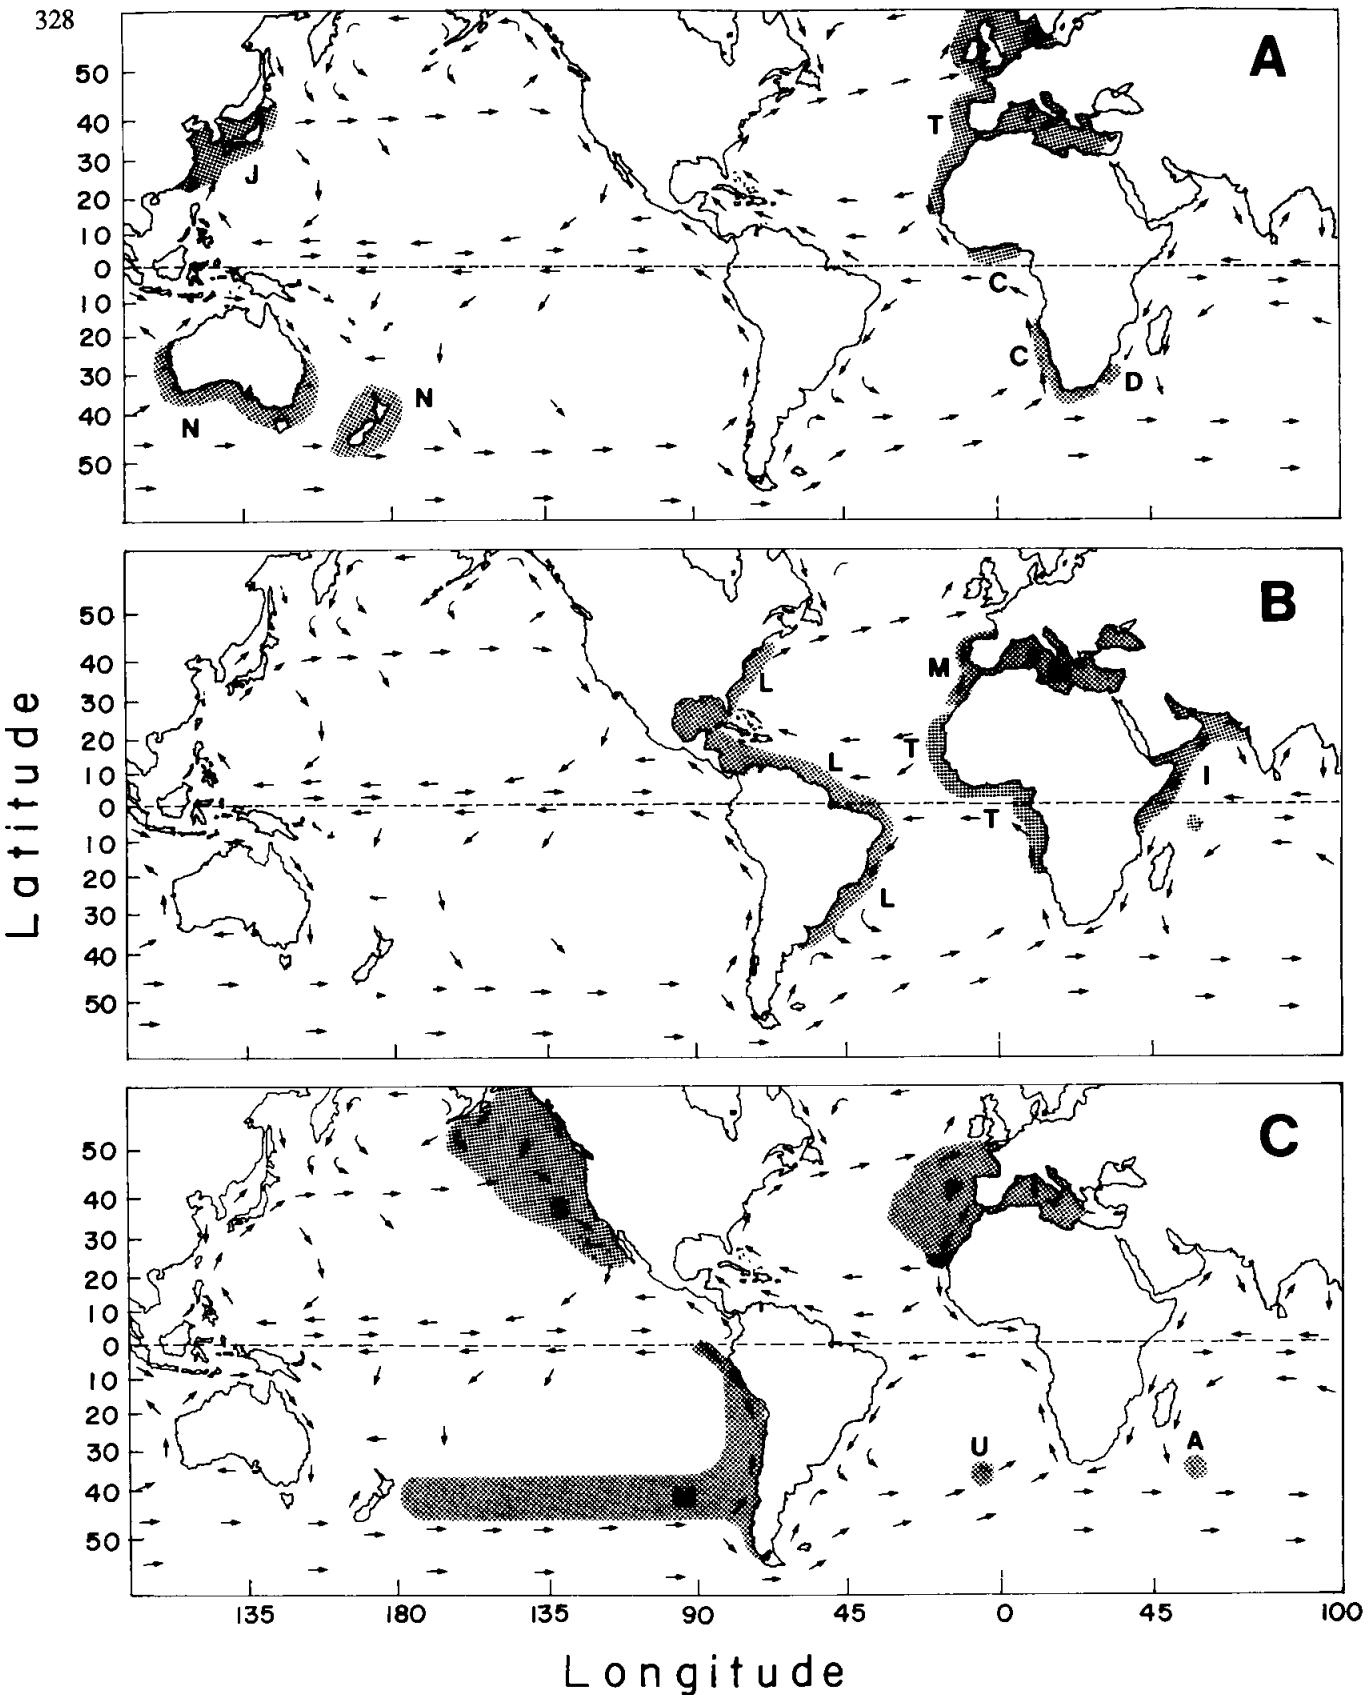

Fig. 4. Geographical distribution of trachurids: A. Shaboneyev's (1980) "trachurus" group: *trachurus* (T), *capensis* (C), *novaezelandia* (N), *japonicus* (J) and *delagoa* (D). B. Shaboneyev's (1980) "mediterranean" group: *mediterraneus* (M), *lathami* (L), *trecae* (T), and *indicus* (I). C. Oceanic horse mackerel: *picturatus* (P), *symmetricus* (S), *murphyi* (M), *aleevi* (A) and unnamed (U).

Fig. 4. Distribución mundial de trachuridos: A. Grupo "trachurus" de Shaboneyev (1980): *trachurus* (T), *capensis* (C), *novaezelandia* (N), *japonicus* (J) y *delagoa* (D). B. Grupo "mediterraneo" de Shaboneyev (1980): *mediterraneus* (M), *lathami* (L), *trecae* (T), y *indicus* (I). C. Jureles oceánicos: *picturatus* (P), *symmetricus* (S), *murphyi* (M), *aleevi* (A) y sin nombre (U).

Stephenson and Robertson (1977) showed that *T. muccullochi* was a junior synonym of *T. novaezelandia* and they found no grounds for distinction between *T. novaezelandia* and *T. japonicus*. They did not formally synonymize these forms apparently due to the fact that there is no gene flow across the present day Indo-Pacific gap in their distributions and they felt this necessitated retaining both species. Stephenson and Robertson (1977) also point out the close similarities between *japonicus*, *novaezelandia* and *lathami*.

There is a general consensus that the members of the *picturatus* or oceanic group are very closely related. Shaboneyev (1980) even states that the members of this group are morphologically so similar that it is difficult to identify them. This consensus rapidly disappears when it comes to deciding whether each is a distinct species or whether they differ at some lower level. Early workers (Jordan and Evermann 1896; Meek and Hildebrand 1925) considered them a single species (*T. picturatus*). Nichols (1940) tried to have it both ways by listing them as separate species but concluded by suggesting that *symmetricus*, *murphyi* and perhaps *declivis* might stand as races of *T. picturatus*.

Roedel and Fitch (1952) found minor differences between the relative size of scutes in *symmetricus* and *murphyi* but were unable to distinguish *symmetricus* from *picturatus*. Berry and Cohen (1974) gave all three the status of species but considered *murphyi* to be an ecotype of *picturatus* and considered *murphyi* and *symmetricus* to be an antitropical species pair. In contrast, Kotlyar's (1976) extensive morphological analysis of the Peruvian horse mackerel concluded that *murphyi* was not sufficiently different from *symmetricus* to merit species rank and he considered it to be a subspecies (*T.s. murphyi*).

According to Shaboneyev and Kotlyar (1979), Aleyev (1957) considered the eastern Pacific forms to be a subspecies of *picturatus* and he also considered the northern and southern Atlantic forms of *picturatus* to be separate subspecies. In their morphological analysis of the eastern Pacific forms of *Trachurus* (i.e., *symmetricus* and *murphyi*) and the oceanic horse mackerel (*picturatus*), Shaboneyev and Kotlyar (1979) state: "our data, based on a considerably greater amount of material, show overlap in all the characters investigated between the oceanic horse mackerel and the eastern Pacific forms of the genus *Trachurus*". However, they found differences in the number of gill rakers which they felt almost reached the subspecies level and differences in the length of the dorsal branch of the lateral line which reached the subspecies level. Although they admitted that they did not find sufficient morphological reasons for considering the eastern Pacific forms and *picturatus* as distinct species, they concluded by suggesting that the ecological differences between them was great enough to merit species rank for the Atlantic and Pacific forms. Their reasons for this conclusion were as follows:

- They considered that *picturatus* differed from the eastern Pacific forms in that it is a neritic-oceanic form widely distributed not only on the continental shelf but also far beyond its boundaries.
- This distribution demonstrated that *picturatus* may live in different water masses, for example, in the cold Canary Current, and in the subtropical waters south of the North Atlantic Current.
- "The most striking contrast with the eastern Pacific forms is provided by the possibility of the existence of the oceanic horse mackerel in the epicontinental Mediterranean, in water masses characterized by heightened salinity."

Recent work has added further complications to the *picturatus* group. Rytov and Razumovskaya (1984) have described a new subspecies of *picturatus* (*T.p. aleevi*) from the southern Indian Ocean and Evseenko (1987) and Bailey (1989) have shown that *murphyi* occurs in the west wind drift region (along about 40°S) from Chile to New Zealand. According to Rytov and Razumovskaya (1984), "the present grouping of the ocean scads into separate species on the basis of geographic isolation is artificial". They agreed with early authors who recognized only one species of oceanic horse mackerel (*T. picturatus*) which occurs in the eastern North and South Atlantic, the eastern North Pacific, the South Pacific and the southern Indian Ocean.

The distribution of three of the *picturatus* group are presently described; *picturatus* (Shaboneyev and Kotlyar 1979), *symmetricus* (Blunt 1969) and *murphyi* (Serra 1983; and Bailey, in press). Unfortunately the southern Indian Ocean distribution of *aleevi* is not given by Rytov and Razumovskaya (1984), who give only the location of the holotype. The distribution of

picturatus in the South Atlantic is also poorly documented in the literature and it is further confounded by the fact that *T. picturatus bingami* has been synonymized with *T. lathami* (Berry and Cohen 1974; Saccardo 1987). The only verified record found for *picturatus* from the South Atlantic was the holotype of *Decapterus longimanus*, from Tristan de Cunha examined by Berry and Cohen (1974). The distribution of the *T. picturatus* group as described in the above works is obviously underrepresented in the South Atlantic and Southern Indian Ocean (Fig. 4C). Its occurrence along the warm side of the west wind drift regions of the South Atlantic, South Indian and South Pacific suggests that *picturatus* may occur in a continuous band along the west wind drift region from the South Atlantic to Chile.

As shown above, Shaboneyev and Kotylar's (1979) ecological distinction between the Atlantic and Pacific forms of the *picturatus* group is unwarranted as the eastern Pacific forms should also be considered neritic-oceanic fishes in that they have even more extensive offshore distributions than *picturatus*. They occur from the cold waters of the Gulf of Alaska and Southern Chile to the subtropical waters of Southern Baja California and the Galapagos Islands. They also extend offshore from Chile to New Zealand. It is true that they are not known to occur in waters as saline as the Mediterranean. However, since such waters do not occur in the Pacific Ocean, this does not prove that the eastern Pacific forms are not capable of existing in such water. Therefore, Shaboneyev and Kotylar's (1979) arguments appear to be reduced to the fact that *picturatus* and *symmetricus* differ because they are isolated.

In summary, the differences between the various geographical forms of the oceanic horse mackerel are insufficient to warrant breaking the group into more than one species. The species *Trachurus picturatus* would appear to have at least three subspecies or races: *T.p. picturatus* in the northeastern Atlantic, *T.p. symmetricus* in the northeastern Pacific and *T.p. murphyi* in the southern ocean. The southern ocean form may be subdivided into three subspecies or races: *murphyi* in the Pacific, *aleevi* in the Indian and an unnamed form in the Atlantic. The recent large increase in the world's catches of horse mackerels therefore comes almost exclusively from exploitation of *Trachurus picturatus murphyi*.

Table 5. Splitter and lumper classification of the genus *Trachurus*.
Tabla 5. Clasificación desdobladora y englobadora del género *Trachurus*.

| Splitter species (13) and subspecies | Lumper species (7) and subspecies |
|---|--------------------------------------|
| <i>trachurus</i> | <i>trachurus</i> |
| <i>capensis</i> | <i>t. trachurus</i> |
| <i>novaehollandia</i> | <i>t. capensis</i> |
| <i>japonicus</i> | <i>novaehollandia</i> |
| <i>delagoa</i> | <i>n. novaehollandia</i> |
| <i>mediterraneus</i> | <i>n. japonicus</i> |
| <i>m. mediterraneus</i> | <i>n. delagoa</i> |
| <i>m. ponticus</i> | <i>mediterraneus</i> |
| <i>lathami</i> | <i>m. mediterraneus</i> |
| <i>trecae</i> | <i>m. ponticus</i> |
| <i>indicus</i> | <i>lathami</i> |
| <i>picturatus</i> | <i>trecae</i> |
| <i>p. picturatus</i> | <i>indicus</i> |
| <i>p. aleevi</i> | <i>picturatus</i> |
| <i>symmetricus</i> | <i>p. picturatus</i> |
| <i>murphyi</i> | <i>p. symmetricus</i> |
| <i>declivis</i> | <i>p. murphyi</i> |
| | <i>p. aleevi</i> |
| | <i>p. unnamed</i> |
| | <i>declivis</i> |

After reviewing the available literature, in my opinion, a definitive analysis of the relationships between the *Trachurus* occurring in different geographical regions cannot be made without a properly designed biochemical genetics analysis. In the absence of such an analysis, the division of the genus into species is probably more a function of the philosophy of individual authors rather than the genetic relationships among the various populations. Therefore, I have included two classification schemes: one for splitters and one for lumpers (Table 5). I also note that considerable further lumping within the *trachurus* and the *mediterraneus* groups may be in order, perhaps even to the three species suggested by Nichols (1940).

Abstract

The relationships between environmental fluctuations and the diet, pup production, mortality and weights of South American fur seals in Peru are examined. Data were collected between 1982 and 1988, covering two El Niño events and three cold years. Fur seal diet, as assessed from scat analyses, varied as a result of changes in availability of anchoveta (*Engraulis ringens*) at sea. When anchoveta were not available, fur seals took a wider range of prey. When anchoveta were abundant, fur seals ate little else. Annual pup production on the study beach ranged from 1,381 to 2,171. Pup mortality during the breeding season (October-December) ranged between 29 and 46%. Within any given year, mortality during the breeding season was correlated to adult female density, but there was no similar relationship between years. There was a significant correlation between pup weights and sea surface temperatures. Availability of prey, particularly anchoveta, appears to affect fur seals' foraging and reproductive performance.

Resumen

Las relaciones entre fluctuaciones ambientales y la dieta, la producción total, mortalidad y pesos de crías de lobo fino de Sudamérica (*Arctocephalus australis*) son examinadas. Los datos fueron colectados entre 1982 y 1988 y cubren dos eventos El Niño y tres años fríos. La dieta de los lobos, estimada a partir del análisis de heces, fue afectada por cambios en la disponibilidad de anchoveta (*Engraulis ringens*). En años cuando la anchoveta estuvo escasa, la dieta de los lobos fue más variada. Cuando la anchoveta fue abundante, casi no comieron otra cosa. La producción anual de crías en la playa estudiada estuvo entre 1,381 y 2,171. La mortalidad de crías fue de 29-46%. Dentro de cada año, la mortalidad durante la temporada de reproducción estuvo relacionada con la densidad de hembras adultas. Se halló una relación significativa entre la temperatura superficial del mar y el peso de las crías. La disponibilidad de presa, en especial de anchoveta, parece afectar el suceso reproductivo y de alimentación de los lobos marinos en Perú.

Introduction

Like other members of the Family Otariidae (fur seals and sea lions), fur seals breed on land and forage at sea. They have long lactation periods (3-36 months), their pups grow slowly (0.05-0.10 kg/day) and females feed intermittently while suckling their young on land (Gentry et al. 1986). This reproductive strategy makes fur seals vulnerable to fluctuations in food availability at sea. Mothers replenish their fat reserves regularly in order to raise their young and thus depend on a constant food supply to breed successfully.

The South American fur seal (*Arctocephalus australis*, Zimmerman 1783) is found in the most diverse range of habitats of any fur seal. It occurs all around southern South America, from sub-tropical Peru, around Cape Horn and the Falkland Islands (Malvinas) and up to southern Brazil, covering a latitudinal range of about 35° (Majluf and Trillmich 1981). However, little is known about the ecology of South American fur seals and what limited information is available comes mainly from studies of the population in temperate Uruguay (Vaz-Ferreira 1956, 1971, 1982; Ximenez et al. 1984; Ponce de Leon 1984). The Peruvian population is of particular

*Present address: Dept. de Biología, Universidad Peruana Caetano Heredia, Apt. 5045, Lima 100, Perú.

interest because it is the only one, along with that of the Galapagos fur seal (*A. galapagoensis*), which breeds on or close to the equator (Bonner 1981).

The presence of fur seals in Peru is linked to the flow of the cold Peruvian (Humboldt) current along the west coast of South America (Majluf and Trillmich 1981). This current dramatically affects the climate and productivity of coastal Peru by reducing air and sea surface temperature (SST) and giving rise to the richest upwelling system in the world (Idyll 1973; Cushing 1982; and see contributions in Pauly and Tsukayama 1987). This system sustains a large biomass of pelagic fish dominated by a single species, the Peruvian anchoveta (*Engraulis ringens*), which supports, in turn, large populations of seabirds and marine mammals (Idyll 1973; Tovar et al. 1987; Muck and Fuentes 1987).

By breeding in Peru, however, fur seals face unpredictable fluctuations in food supply. At variable intervals of between 2 to 7 years, the upwelling system is affected by major oceanic perturbations known as El Niño events (Cane 1983; Brainard and McLain 1987; Bohle-Carbonnel, this vol.). These affect the ecosystem by increasing SST and directly affecting the depth distribution and abundance of anchoveta, among other things. The effects of El Niño events on the Peruvian seabird populations and fisheries have been well documented (Cushing 1982; Arntz et al. 1985; Tovar et al. 1987; Muck and Pauly 1987; and other contributions in Pauly and Tsukayama 1987), but less is known about how fur seals in Peru are affected by these changes (Limberger et al. 1983; Majluf 1985; Trillmich et al. 1986).

This study examines how the Peruvian population of the South American fur seal has adapted to its environment by looking at its ecology and behavior, particularly how changes in food availability affect the fur seals' diet, pup production, mortality and weight. This could be done in the frame of a relatively short 6-year study because sea conditions varied widely during this period (1982-1988, see below). Only limited information was obtained during the severe 1982/1983 El Niño events; but where relevant, data from these years were included to show how conditions of extreme food shortage affected fur seals. One must bear in mind, however, that the 1982/1983 El Niño event was exceptionally strong, and that, its effects are likely to be considerably greater than those of previous events.

The study was carried out at Punta San Juan (PSJ, 15°22'S, 75°12'W, Fig. 1), which holds up to 50% of the fur seals in Peru (Majluf and Trillmich 1981). PSJ is the area of coldest waters, most intense upwelling (Zuta et al. 1978) and highest primary productivity (Cushing 1982) off the coast of Peru.

Methods

Data were collected between January 1983 and December 1988 as part of a long term study of the breeding ecology of fur seals. The methods used are described in detail in Majluf (1987) but a brief description is given here. Sea surface temperature (SST) data were kindly provided by Comdte. Hector Soldi (Department of Oceanography, Peruvian Navy).

Years mentioned in the text cover the breeding season when a given cohort was born and January, February and March of the subsequent year (e.g., 1985 includes data collected from October 1985 until March 1986). Survival data cover the period from birth to the following September. The 1982 data do not cover the breeding season; the 1983 data include January to August 1983 only.

From 1984 on, each year after the breeding season (late December) 200 pups were weighed and individually marked using plastic numbered tags (Allflex Medium) in both front flippers. Additionally, between 50-300 pups were weighed monthly between November and March.

Fur seal diet was studied from the analysis of hard parts (fish otoliths and squid beaks) found in fresh scats. Prey items were ranked by frequency of occurrence in the scats except for 1983 when the scats were not studied individually (they had been pooled before analysis). In 1983, the prey items were ranked by the proportion of the total number of otoliths belonging to particular prey species. Anchoveta (*Engraulis ringens*) length distributions from the fisheries were kindly provided by Ms. Isabel Tsukayama (IMARPE). Only data from 1983, 1984 and 1985 are presented here (see Tsukayama and Palomares 1987, for time series of length data covering the years 1953 to 1982 and Pauly and Palomares, this vol. for an update to 1987).

In January/February 1983, pup mortality under El Niño conditions was estimated from daily counts of dead pups on one beach at PSJ. Survival between February and March 1983 was estimated from resightings of pups tagged on another beach ($n = 14$), between 7-10 February, and resighted on the 7th March.

From 1984 onwards (but excluding 1986), the total number of pups born and mortality throughout the breeding season (mid-October to late December) were estimated from daily counts of freshly dead pups and of placentas observed early in the morning. The number of pups born each day was estimated as twice the placenta count (see Majluf 1987 for rationale). All animals ashore on the study beach (divided by age and sex classes) were censused daily at 6:00 throughout the breeding season. Outside the breeding season, apparent pup survival (i.e., including tag loss and dispersal, 1985-1987 only) was estimated from resightings of tagged pups (tag loss between years was assumed consant).

The statistical analyses were carried out using the SPSS-X statistical package on an IBM mainframe, and STATVIEW and STATWORKS on an Apple Macintosh Plus microcomputer.

Results

Environmental conditions during this study varied dramatically. The years covered include two El Niño events (1982 and 1986), two cold years (1984 and 1987) and a "normal" year (1985, Fig. 2). These variations appear to be related to changes in distribution and abundance of pelagic fish and of the seals' behavior and reproductive performance.

Diet

Between January 1983 and December 1985, 277 scat samples were collected, from which 1,938 otoliths and nine squid beaks were recovered. Twenty species of prey were identified but 86% of the otoliths belonged to only four species of fish: deep sea smelt *Laeuroglossus urotramus* (Bathylagidae) (40%), anchoveta, *Engraulis ringens* (Engraulidae) (34%), sardines, *Sardinops sagax* (Clupeidae) (6%) and "species number 21" which is still unidentified (6%). Other prey species contributed less than 4% of the otoliths (Table 1).

The most important prey items were all less than 30 cm long, weighed less than 300 g and were either epi- or meso-pelagic species known to carry out vertical migrations at night (Fitch and Brownell 1971; Gjøsaeter and Kawaguchi 1980; Jordan 1971; Longhurst 1971). The few demersal species recorded also fell within similar length/weight ranges and are all known to leave the bottom after dark (Leible et al. 1981, Chirichigno et al. 1982).

Diet composition varied widely, but in most (8/12, Table 1) collection periods, anchoveta appeared as the most important item consumed (although *L. urotramus* made up to 40% of the otoliths collected, it was only found in three scats). The numbers and size ranges of otoliths of anchoveta varied between periods. The June and July 1983 samples only included one and four anchoveta otoliths respectively, and thus have not been included in the calculations presented below. When comparing the three years studied, the sizes of anchoveta taken by the seals were found to be significantly different in two of three cases (t-test: 1983 vs 1984: $t = -10.7$, $df = 66$, $P < 0.001$; 1984 vs 1985: $t = 18.5$, $df = 103$, $P < 0.001$; 1983 vs 1985: not significant). No differences in sizes were found within years. When the size distributions of anchoveta for each of these periods were compared with fishery catch data, the 1983 and 1985 samples closely matched the fishery catch composition for the same time periods while the 1984 sample was shifted to the left (Fig. 3). In 1983 and 1985, fur seals took mostly adult anchovetas (about 15 cm long), while in 1984, they took smaller fish.

^aSpecies given as numbers have not been identified.

^bRank based on frequency of occurrence, except for 1983 when it is based on number of otoliths because the samples collected that year were not analyzed individually.

Diet diversity varied with the most important item taken. In the periods when adult anchoveta were the most important prey (January-March 1983 and September-October 1985, Table 1), the number of species in the diet was less ($\bar{x} = 4.5$, 0.8 species of prey/period, $n = 6$) than when smaller anchovetas or other species of prey were the most important prey items ($\bar{x} = 8.2$, 1.1 species of prey/period, $n = 6$). This difference was significant (Mann-Whitney $U = 4.5$, $P < 0.01$).

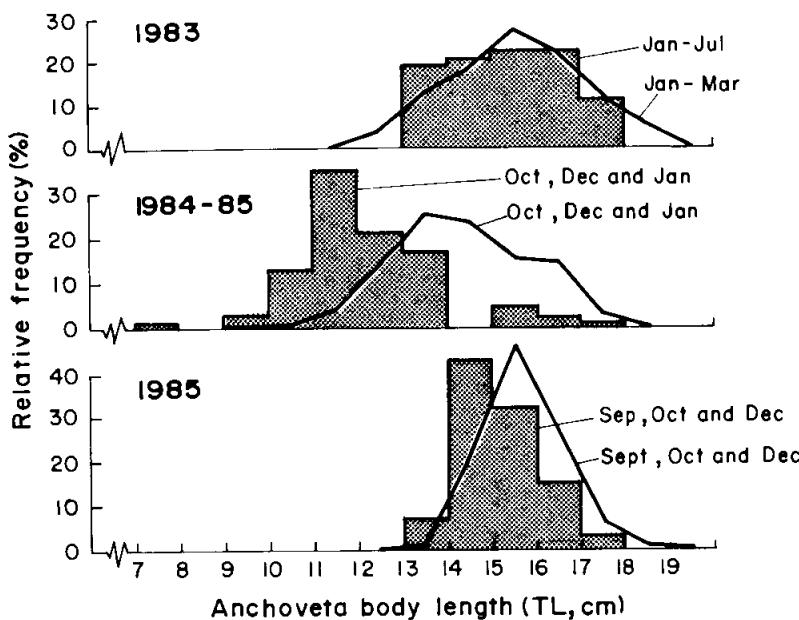

Fig. 3. Length-frequency distribution of anchoveta eaten by fur seal (shaded histograms) as reconstructed from otoliths recovered from scats compared with the fishery catch size distribution in a comparable period (solid line, unpublished IMARPE data). Note rough correspondence in 1983 and late 1985 and shift toward smaller sizes in 1984 and 1985.

Fig. 3. Distribución de frecuencias de longitud de las anchovetas comidas por los lobos finos (histogramas sombreados), obtenidos de los otolitos recuperados de las heces, comparadas con la distribución de frecuencia de longitud de la anchoveta capturada por la pesquería (líneas sólidas, IMARPE datos inéditos). Notar correspondencia aproximada en 1983 y 1985 y el cambio hacia tamaños más pequeños en 1984 y 1985.

The periods when adult anchovetas were missing from the fur seals' scats were related to periods when they were not available to the fisheries. Adult anchovetas did not occur in the scats during the winter in 1983 (June-August), nor during the spring and summer of 1984/1985 (October-January), when the seals took only very small anchoveta. Environmental conditions in these two periods were very different but in both cases, it is possible to relate them to a low availability of adult anchoveta. During the El Niño event of 1982/83, in June 1983, the few anchoveta that had been present in January-February were either dead or had migrated south (Arntz 1986; Vilchez et al. 1988). Also during the winter, even in "normal" years, anchoveta become less available as they disperse when the warm water front moves away from the coast (Zuta and Urquiza 1978; Muck et al. this vol.) and the thermocline deepens (Mayers 1979; Cane 1983; Chavez 1987; Brainard and McLain 1987). With the information available, it is not possible to separate the El Niño effects from the normal winter dispersion. In 1984, no anchoveta were taken by the fisheries around PSJ (Pedro Llarena, pers. comm.) but the seals took small anchoveta, probably the first recruits following the 1982/83 El Niño event.

The periods when adult anchoveta did occur in the diet (January-April 1983 and September-December 1985) can be related to a relatively high availability of anchoveta in the area. In March, early on during the 1983 El Niño, a survey of the entire Peruvian coast carried out by IMARPE showed anchoveta schools only near PSJ, close to shore (IMARPE, unpubl. data). In 1985, surveys conducted by IMARPE reported the highest anchoveta biomass since the 1972/73 collapse (Vilchez et al. 1988). Preliminary analysis of the scats collected in 1987 suggest a similar abundance of anchoveta around PSJ (P. Vasquez, pers. comm.).

Pup Production and Mortality

The number of pups born per year on the study beach at PSJ ranged between 1,381 and 2,171 (Table 2). The differences between years could be related either to changes in the number of females coming to breed ashore or to variations in female fertility. There was no correlation between the peak number of females ashore during the breeding season and the number of births recorded. The highest number of females was observed in 1985 while pup production was highest in 1988.

There were no correlations between the number of pups born and mortality or peak number of females ashore during the breeding season (Table 2). The highest mortality was observed in 1987 when 46.5% of the pups (0-30 days old) died before the end of the breeding season. In general, mortality within the breeding period was high, never less than 29%. Outside of the breeding season, mortality was low, about 2% per month.

Most pups born during the breeding season, but before the 15th of October were stillborn or died within two days of birth. Mortality decreased from mid-October to mid-November, then picked up steadily again; peak mortality was reached in late November, when the highest numbers of females ashore were observed. For all four years, daily counts of females ashore were significantly correlated with the number of dead pups counted on the same day (Fig. 4). At peak female densities, mortality was highest.

Pup mortality outside the breeding season (January-March) was high only in 1982, during El Niño. Of about 70 pups on one beach, at least 29 (41%, not counting those washed out to sea) were seen dead on land between January and February. Afterwards, of 14 pups tagged in early February on another beach, only three (21%) were resighted by March. Only one of these three was resighted the following year.

Table 2. Comparison of environmental conditions/food availability, number of births, pup mortality, and number of females ashore during the breeding season on one beach at PSJ between 1982 and 1988.

Tabla 2. Comparación de condiciones ambientales/disponibilidad de alimento, número de nacimientos, mortalidad de crías, número de hembras en tierra y pesos de crías en una playa de PSJ entre 1982 y 1988.

| Year | SST ^a / Food availability | Births | Death/% Mortality | Females ashore ^b |
|-------------------|---|--------|----------------------|--------------------------------|
| 1984 | Cold/rich | 1,381 | 538 / 38.9 | 433 ± 8 |
| 1985 | Normal/medium | 1,704 | 693 / 40.7 | 547 ± 6 |
| 1987 | Cold/rich | 1,700 | 790 / 46.5 | 514 ± 10 |
| 1988 ^c | Cold/rich | 2,171 | 645 / 29.7 | 533 ± 11 |

^aIf SST anomalies between January - March are positive, SST = Hot (> 2°C) or warm. If they are negative and greater than 1°C, SST = cold (Fig. 2). Cold = rich (high food), warm = poor (low food availability).

^bNumber of females ashore = mean (± s.e.) of daily counts of females ashore at 06:00 between 21-30 November at peak female densities.

^cSeptember to December 1988 only, weight data not analyzed yet.

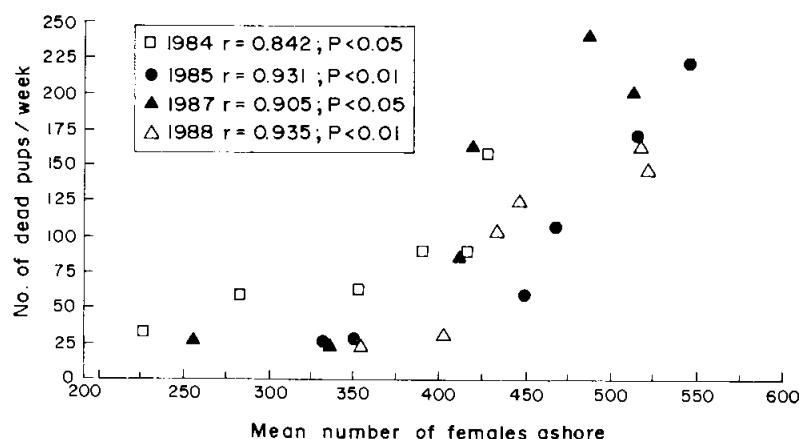

Fig. 4. Correlation between number of dead pups counted on one beach at Punta San Juan (total for a 7-day interval) during the breeding season (Oct.-Dec.) and the mean number of females ashore during the same interval (1984-1988).

Fig. 4. Correlación entre número de crías muertas contadas en una playa de Punta San Juan (total para un intervalo de 7 días) durante la temporada de reproducción (Oct.-Dic.) y el número promedio de hembras en tierra para el mismo intervalo (1984-1988).

In subsequent years, even under varying environmental conditions (see above), pup survival rates outside the breeding season were much higher and did not vary much between years. Fig. 5 shows the survival rates of pups tagged in 1985, 1986 and 1987. Between 40-50% of the pups born survived to one year of age. The lower survival in 1987 was due to the high mortality during the breeding season.

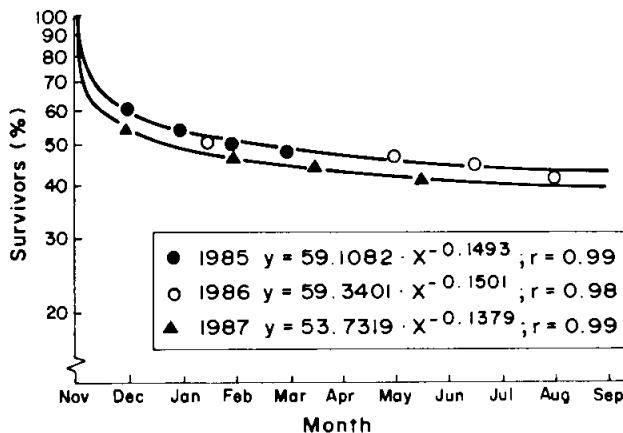

Fig. 5. Estimated survival of fur seal pups from November to September of the next year. (Note that upper curve represents both 1985 and 1986 cohorts; tag losses may suggest a lower survival than actually occur).

Fig. 5. *Sobrevivencia estimada de crías de lobo fino entre Noviembre y Septiembre del año siguiente. (Notar que la curva superior representa la supervivencia de las cohortes de 1985 y 1986; la pérdida de marcas podría sugerir una menor supervivencia que la que ocurre realmente).*

Pup Weight

Pups were born with a weight between five and seven kg and males were always heavier than females. Birth weights, however, varied between years (Table 3). The higher weights occurred in the cold years, in 1985 and 1987; the lowest in 1982 and 1986, during El Niño years. There was a significant negative correlation between SST and the weights of 90-day-old pups in February (the only month when weight was collected in all years, Fig. 6). In 1982, the very low weights resulted in higher mortality.

Table 3. Weight of 0-120 days old pups (1982-1987).
Tabla 3. Peso de crías de 0-120 días de edad en PSJ (1982-1987).

| Age (days) | Year | Females | | | Males | | |

Discussion

As was clearly observed, in spite of the short duration of this study, environmental conditions in the Peruvian upwelling system are highly variable. Changes in SST affect the availability of food resources to the fur seals and are reflected in changes of their diet, mortality and growth.

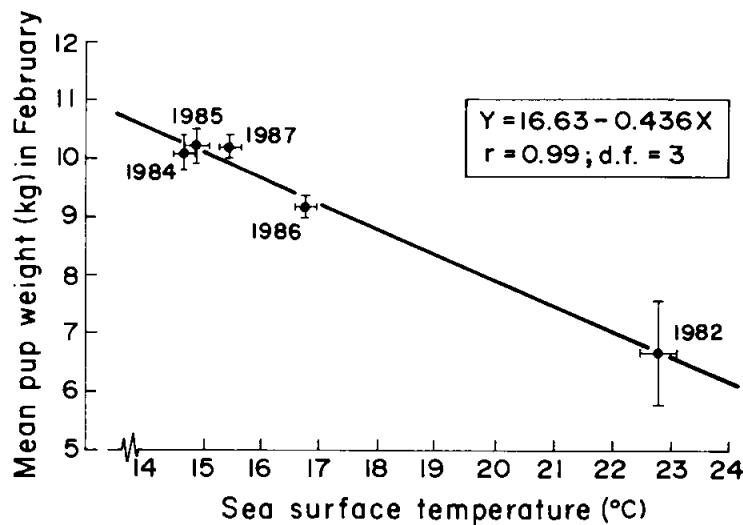

Fig. 6. Relationship between mean February fur seal pup weight and sea surface temperature near Punta San Juan, Peru.

Fig. 6. Relación entre el peso promedio de crías de lobos marinos en Febrero y la temperatura superficial del mar cerca a Punta San Juan, Perú.

Diet

Studies of the northern fur seal (*Callorhinus ursinus*, Kajimura 1984) and of the California sea lion (*Zalophus californianus*, Antonelis et al. 1984; Bailey and Ainley 1982) for which concurrent data on food availability exist, have shown that the relative proportion of a specific prey item in the diet reflect availability and abundance of that item at sea. This apparently is also the case for the fur seals at PSJ. Although information on changes in availability of anchoveta for the area around PSJ is limited, the data here suggest that there is a relationship between the fur seals' diet, as described from faecal material, and prey abundance and availability. Also, it is apparent that South American fur seals at PSJ prey almost exclusively on small epi- or mesopelagic fish, apparently with preference for adult anchoveta.

In eight of twelve sampling periods, anchoveta was the most important (i.e., most frequently occurring) prey. Diet diversity was apparently related to whether or not adult anchoveta were available at sea. In the periods when adult anchoveta were not the most frequently occurring item in the scats, a wider range of prey was taken and these coincide with the periods of reported anchoveta scarcity. In contrast, when adult anchoveta were abundantly available to the fisheries, fur seals took few other prey (84% of all otoliths recovered from the scats in 1985 were from adult anchoveta). Optimal foraging theory predicts, among other things, that predators should be more selective when food is abundant than when it is scarce (MacArthur and Pianka 1966; Krebs 1978). An increase in the diversity of species taken when the preferred prey item (hake) was not available has been shown to occur in the California sea lion (Bailey and Ainley 1982).

Thus, despite the dramatic decrease in biomass of anchoveta off the Peruvian coast since 1972 (Cushing 1982; Pauly et al. 1987), fur seals apparently still show a preference for anchoveta. Changes in the availability or abundance of this resource thus affect fur seals. When anchovetas are scarce, they have to take a wider range of prey.

Also, during El Niño events, even if adult anchoveta are available in sufficient density, fur seals will obtain less energy from the same number of fish because the condition of anchoveta is poor, resulting in a lower calorific content (Palomares et al. 1987).

Birth and Mortality Rates

The total number of births recorded varied between the four years studied. These differences could be due to changes in female fertility or in the number of females using the study beach to give birth each year. There was no correlation between births and number of females ashore,

therefore, changes in female fertility could have taken place between the years studied. With the information available, it is not possible to show this, but changes in female fertility as a result of variations in the environment or in the condition of the females have been shown in the Galapagos fur seal (Trillmich and Limberger 1985).

Pup mortality within the breeding season was high and varying in all years in a similar pattern. All pups born before mid-October were either stillborn or died within two days. Mortality peaked around late November, when female densities were highest.

High female densities and female thermoregulatory movements appear to be the main causes of the high pup mortality observed near the end of the breeding season. When the highest pup mortality was observed in late November, most females ashore had just given birth and were in their perinatal attendance period (approximately 8-10 days after giving birth, during which they remain fasting on land, suckling their pups) during which they are very aggressive towards any approaching seal. This aggression is exacerbated by the need to reach the water's edge for thermoregulation. This is so because their adaptations to avoid hypothermia while at sea adversely affect thermoregulation while they are on land. At high air temperatures, avoiding the sun and getting wet are among the most effective behavioural mechanisms to maintain thermal balance in otariids (Whittow et al. 1971; Limberger et al. 1986). At PSJ, there are only a few small caves and large boulders providing shade at the back of each beach. Therefore, the main means of thermoregulation for most animals is to wet their fur.

Females who give birth in areas with no access to water are forced to make daily excursions to and from the water's edge. These movements increase the probability of mortality of newborn pups, especially around the peak of pupping, when densities are highest. Females carrying pups in their mouths and trying to reach the water are attacked by other females while in transit. Often, the pup is dropped among other pups and confusion arises. It is very common to observe females fighting over pups, or "foreign" pups being thrown about by females who do not want them near. Later in the season, aggression appears to decrease as most of the females go to sea to forage and only a smaller portion of the female population remains on land (Majluf 1987).

High densities and crowding during the breeding season has been shown to be an important cause of mortality in other species of pinnipeds. Studies of Antarctic fur seals (*A. gazella*, Doidge et al. 1983), elephant seals (*Mirounga angustirostris*, Le Boeuf and Briggs 1977) and grey seals (*Halichoerus grypus*, Anderson et al. 1979) suggest that the proximate cause of mortality at high density sites or crowded situations is the higher probability of losing the pup and the "trauma-starvation" syndrome (injury, starvation and infections as a result of separation from the mother, Le Boeuf and Briggs 1977). The results from this study also suggest that mortality may be related to female movements at high densities causing the separation of mother and pup.

Mortality within the first month of life in all other species of fur seals does not exceed 20% (Majluf 1987). Thus, the 29-46% mortality reported here is exceptionally high. Within PSJ, almost 60% of the fur seals breed on the study beach. The amount of space available for females and their pups on this beach is limited by the need to have access to water for thermoregulation. Thus, in the hot hours of the day, females are concentrated in about one third of the beach area (approximately 0.5-1 female per m²). Though densities in other fur seal rookeries may be similar or even higher (*Callorhinus* at St. George, M. Goebel, pers. comm.; *A. gazella* on Bird Is., J.P. Croxall, pers. comm.), the females there do not have to undertake daily thermoregulatory movements. Hence, the number of interactions with other aggressive females and therefore, mortality, are lower (Costa and Trillmich 1988).

If female density is related to pup mortality during the breeding season, there should be a correlation of peak number of females ashore with percentage mortality between years. Such correlation was not found. The highest mortality occurred in 1987 and the highest number of females ashore occurred in 1985. Thus, other factors may determine the differences in percentage mortality between years. The high mortality in 1987 could be related to the El Niño conditions in the previous year. Pup weights were lower; possibly these weaker pups were less able to survive the breeding season than in other years. Unfortunately, there is no data for the 1983 breeding season, following the intense 1982/83 El Niño event.

After the breeding season, mortality was much lower except for 1982 during El Niño, when pups died of starvation throughout the year (Majluf 1985). Subsequently, even under varying

environmental conditions (survival data were collected in 1985, 1986 and 1987, i.e., during "normal", warm (poor) and cold (rich) years, respectively), survival rates outside the breeding season did not differ between years. The higher mortality during the 1982 El Niño was mainly due to starvation caused by the long absence of mothers foraging at sea (Majluf 1985; Trillmich et al. 1986). In the case of milder El Niño events such as the one in 1986, pelagic fish tend to concentrate in areas where cold upwelled waters persist, particularly around PSJ (Villanueva et al. 1969; Vilchez et al. 1988). Thus, females at PSJ might be able to forage close to shore and return to their pups often enough to avoid their starvation. More information is needed to understand the factors determining survival outside the breeding season.

Pup Weights

Variations in SST were correlated to changes in pup weights. Pup weights and growth rates are indirectly affected by changes in prey availability at sea. If the mothers are not able to hunt efficiently, they either take longer to obtain enough food to cover their own and their pups' metabolic demands, or they return ashore with less or lower quality milk (Trillmich and Limberger 1985; Gentry et al. 1986). In either case, the pups' growth is slower and this is reflected in the recorded weights. In extreme cases, such as during the 1982/83 El Niño event, a decrease in food availability resulted in increased mortality. During events of lesser intensity, pup growth is impaired but survival in the first year of life seems not to be affected.

Conclusions

The results of this study indicate a relationship between fluctuations in prey availability at sea and the fur seals' behavior and reproductive performance. PSJ is an exceptional area because cold waters tend to persist in this area even under El Niño conditions. Thus, while even mild El Niño events may have a negative effect on the seals further north along the Peruvian coast (Muck and Fuentes 1987), at PSJ, the seals may benefit from such conditions. If fish are concentrated in the area, seals might find it easier to forage under mild El Niño conditions. If the event is as intense as the one in 1982/1983, however, even at PSJ, fur seals will be negatively affected.

Like many other marine vertebrates in the Peruvian upwelling system, fur seals have adapted to feeding mainly on anchoveta, a species once abundant in this system. A lower availability of this resource causes fur seals to take other less energetically profitable prey, and/or to spend more energy foraging and this decreases pup growth. Although the differences in growth did not appear to be reflected in survival in the first year (except in 1982), survival and/or reproductive success later in life might be affected. Smaller animals are less able to forage efficiently than larger ones (Kooiman et al. 1983; Gentry et al. 1986; Majluf 1987). Thus, a decrease in food availability is likely to have a greater effect on smaller individuals learning to forage independently after weaning (about 6 months to 3 years). Also, smaller animals may have lower reproductive success when adults. Smaller males are less able to compete for territories and therefore, have limited access to females (Majluf 1987). Small females have less fat resources than larger females and may be less able to sustain a pup in poor years. Thus, variations in anchoveta availability may affect the fur seals foraging and breeding performance. To test these various hypotheses, more information is needed on the changes (yearly, seasonal and daily) in anchoveta distribution and abundance around PSJ before definitive conclusions can be drawn.

Acknowledgements

I am grateful to all those who have collaborated in this study between 1982 and 1988, especially to Mike Goebel (Nat. Marine Mammal Lab., NOAA, NWAWS), Rob Harcourt (University of Cambridge), Pedro Vasquez (U. Nac. Agraria, La Molina) and Pedro Llerena. To Rob Harcourt, many thanks for his multiple revisions of the manuscript and constructive

criticism. Thanks also to the Peruvian Navy, the Ministry of Fisheries, the government agencies, Pesca-Peru and Hierro-Peru for their logistic support and to the IMARPE staff, notably Ms. I. Tsukayama for unpublished data. The first years of this study (1982-1985) were carried out as part of my Ph.D dissertation at the Department of Zoology, Large Animal Research Group in Cambridge, England, supervised by Drs. T.H. Clutton-Brock, J.P. Croxall (British Antarctic survey) and S.S. Anderson (Sea Mammal Research unit). Funding was granted by Wildlife Conservation International (a division of the N.Y. Zoological Society).

Abstract

This paper reviews the status, distribution and ecology of marine mammals in Peruvian waters. Although very little is known about most species of marine mammals in Peru, all the common species are or have been directly exploited. Seal and large whale populations were severely depleted but are now legally protected. The effect of exploitation on the legally unprotected small cetaceans remains unknown. Marine mammals are top predators in the marine ecosystem and feed primarily on small pelagic fish or squid. Most Peruvian small cetaceans and pinnipeds feed primarily on anchoveta (*Engraulis ringens*) which was depleted by a combination of overfishing and a strong El Niño event. The lower prey availability may prevent marine mammal species from recovering to their former population levels. For adequate management of these marine mammal populations, more information is needed. Tourism (whale and seal watching) is suggested as an alternative nonconsumptive use of these animals.

Resumen

Este artículo hace una revisión del status, distribución y ecología de los mamíferos marinos en aguas peruanas. Aunque se sabe muy poco sobre la mayoría de especies de mamíferos marinos en el Perú, todas las especies comunes son o han sido explotadas comercialmente. Los lobos marinos y los grandes cetáceos fueron casi extirnados pero en la actualidad se hallan protegidos legalmente. Aun se desconoce el efectos de la caza sobre las poblaciones de pequeños cetáceos quienes no cuentan con ninguna protección legal. Los mamíferos marinos son los predadores tope del ecosistema y se alimentan primordialmente de pequeños peces pelágicos y de calamares. En el Perú, la mayoría de pequeños cetáceos y pinnípedos se alimentan principalmente de anchoveta (*Engraulis ringens*), cuya población fue casi extinguida por la sobre pesca combinada con los efectos de "El Niño". La menor disponibilidad de anchoveta en la actualidad puede limitar la recuperación de las poblaciones de mamíferos marinos a sus niveles previos. Para el manejo adecuado de estas poblaciones, es necesaria mayor información. Se sugiere al turismo (tours para observar ballenas y lobos marinos) como una alternativa no-destructiva para el uso de los mamíferos marinos.

Introduction

As a consequence of human activities throughout the world (both direct exploitation and disturbances), some marine mammal species (whales, dolphins, seals, otters and sirenians) have become extinct, and many populations are seriously depleted. Hence, there is a need to determine the status of the remaining marine mammal populations, to measure the extent of current exploitation and if necessary, implement measures to ensure the preservation of those species most endangered.

Little is known about most marine mammals in Peru. This is despite the fact that high concentrations of whales, seals and dolphins are still found in this area and that most of these species have been exploited for at least the last 50 years. Whaling occurred in Peruvian waters from the 17th century (Clarke 1962) to 1986 and from early in this century, sea lions were

hunted in high numbers for their skins and oil (Gamarra Dulanto 1943; Gonzales Zúñiga 1944; Piazza 1969). They are still hunted illegally by fishermen claiming they get caught in and damage their gear. The Peruvian fisheries for small cetaceans seem to have developed only in the last 15 years partly as a result of the collapse of the anchoveta (*Engraulis ringens*) fishery in the early 1970s and has increased dramatically in recent years due to the deterioration of the economic situation in Peru (Read et al. 1988). However, despite this continuous exploitation of marine mammals in Peru, not even a complete list of the species found in these waters is available and for most, their distribution and abundance remain unknown.

Since 1983, detailed studies of the small cetaceans and seals in the Peruvian upwelling ecosystem have been carried out (i.e., Majluf 1985, 1987, this vol.; McKinnon 1988; Read et al. 1988; Reyes et al. 1988; Van Waerebeek and Reyes 1986, 1988a, 1988b; Van Waerebeek et al. 1987, 1988) and we are starting to learn how the most common species are adapted to this highly variable system. Also, through these studies, several new records of species of marine mammals previously unknown to occur in these waters have been obtained. Here, we will review the available information on the marine mammals in Peru; riverine species (manatees, river dolphins and river otters) are not included. For the most common species, names (spanish common name in italics within brackets), the size, status, distribution, breeding and feeding ecology, and interactions with fisheries will be described. All species known (Table 1), including those which are known only from a few stranded animals, will be listed (for full details, see Van Waerebeek et al. 1988). Fig. 1 provides a map with all locations mentioned in the text. With this review, we hope to provide a better basis for future management plans and to improve the existing protection of these animals.

Table 1. Species of marine mammals recorded from Peru (species with an * are illustrated in Fig. 2).

Tabla 1. Especies de mamíferos marino reportados del Perú (especies señaladas con * están ilustradas en la Fig. 2).

Order PINNIPEDIA

Family *Otariidae*

- **Arctocephalus australis* (Zimmermann 1783)
- **A. philippii* (Peters 1866)
- **Otaria byronia* (Blainville 1820)

Family *Phocoenidae*

- Phocoena spinipinnis* Burmeister 1865

Order CETACEA

Sub-order Mysticeti

Family *Balaenopteridae*

- **Balaenoptera musculus* (Linnaeus 1758)
- **B. physalus* (Linnaeus 1758)
- **B. borealis* Lesson 1828
- B. edeni* Anderson 1878
- **Megaptera novaeangliae* (Borowski 1781)

Family *Delphinidae*

- Lagenorhynchus obscurus* (Gray 1828)
- **Tursiops truncatus* (Montagu 1821)
- **Grampus griseus* (Cuvier 1812)
- **Delphinus delphis* Linnaeus 1758
- Stenella attenuata* (Gray 1846)
- S. coeruleoalba* (Meyen 1833)
- S. longirostris* (Gray 1828)
- Peponocephala electra* (Gray 1846)
- Feresa attenuata* Gray 1874
- Globicephala melaena* (Traill 1809)
- **G. macrorhynchus* Gray 1846
- **Pseudorca crassidens* (Owen 1846)
- **Orcinus orca* (Linnaeus 1758)

Sub-order Odontoceti

Family *Physeteridae*

- **Physeter macrocephalus* Linnaeus 1758
- **Kogia breviceps* (de Blainville 1838)
- K. simus* (Owen 1866)

Order CARNIVORA

Family *Mustelidae*

- **Lutra felina* (Molina 1782)

Family *Ziphidae*

- Ziphius cavirostris* Cuvier 1823
- Mesoplodon grayi* von Haast 1876
- Mesoplodon* sp. (undescribed)

Annotated Species List

Pinnipeds

Arctocephalus australis South American fur seal (*Lobo fino*)

Size: Adult female fur seals in Peru are about 1.4 m long and may reach 90 kg (mean weight = 60 kg, Majluf 1987). No weights for males have been recorded for Peru. In Uruguay, they are

around 1.8 m long and weigh up to 200 kg (Vaz-Ferreira 1982). Newborns weigh between 3.5 and 7.5 kg (Majluf 1987).

Status and distribution: South American fur seals occur all around the southern coasts of South America, from Rio de Janeiro in Brazil to Paracas in Peru (Majluf and Trillmich 1981). There is only limited information on the size of the fur seal population in Peru. At present, the population is recovering from near extinction at the beginning of this century (Murphy 1925). By 1943, only a few small groups of fur seals were found in isolated areas in southern Peru (Gamarra Dulanto 1943; Gonzales Zuñiga 1944). Piazza (1969) reports having found only 40 fur seals in Paracas ($13^{\circ}55'S$) during an extensive seal survey in southern Peru in the early 1950s. Other counts performed in 1961, 1963 and 1964 showed that Paracas was still the most important fur seal colony but a few other small colonies were found south of there. Grimwood (1969) reported Paracas as the only breeding colony with about 2,000 animals but estimated a total fur seal population of 4,000-5,000 (Laws 1973). The latest census of 1984 gives a total of around 15,000 fur seals in Peru (Tovar and Fuentes 1984). This is likely to be a minimal estimate because the censuses carried out by the Peruvian government agencies did not consider seasonal and diurnal variations in numbers of seals ashore.

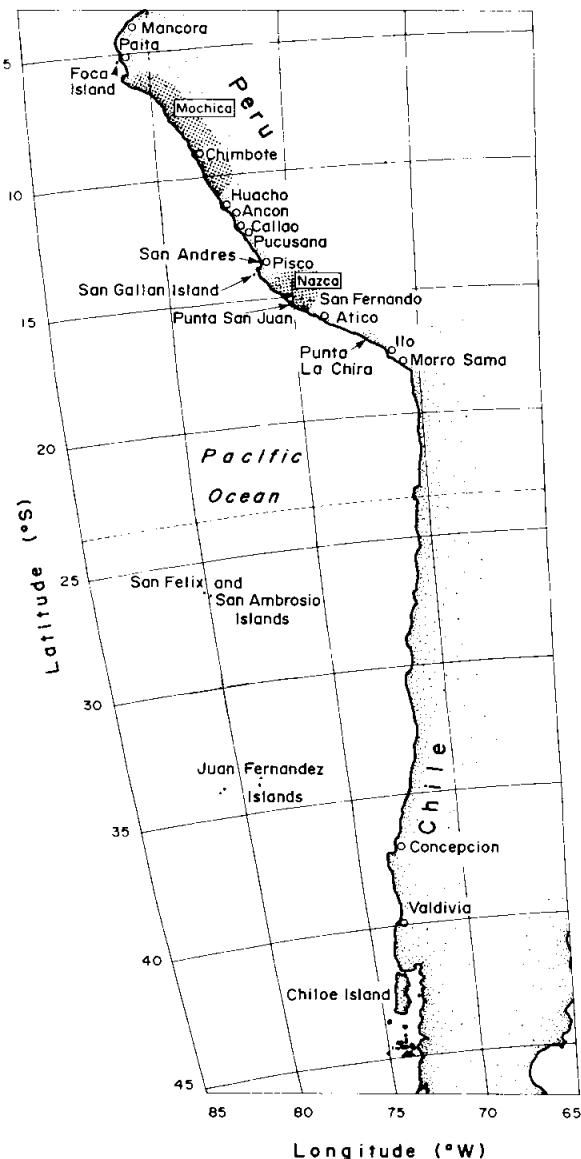

Fig. 1. Partial map of the western coast of South America, showing all locations mentioned in the text of this contribution, as well as the areas previously inhabited by the Mochicas and the Nazcas (shaded).

Fig. 1. Mapa de parte de la costa oeste de Sud América mostrando todas las localidades mencionadas en el texto de esta contribución, así como las áreas ocupadas previamente por las culturas Mochica y Nazca (sombreado).

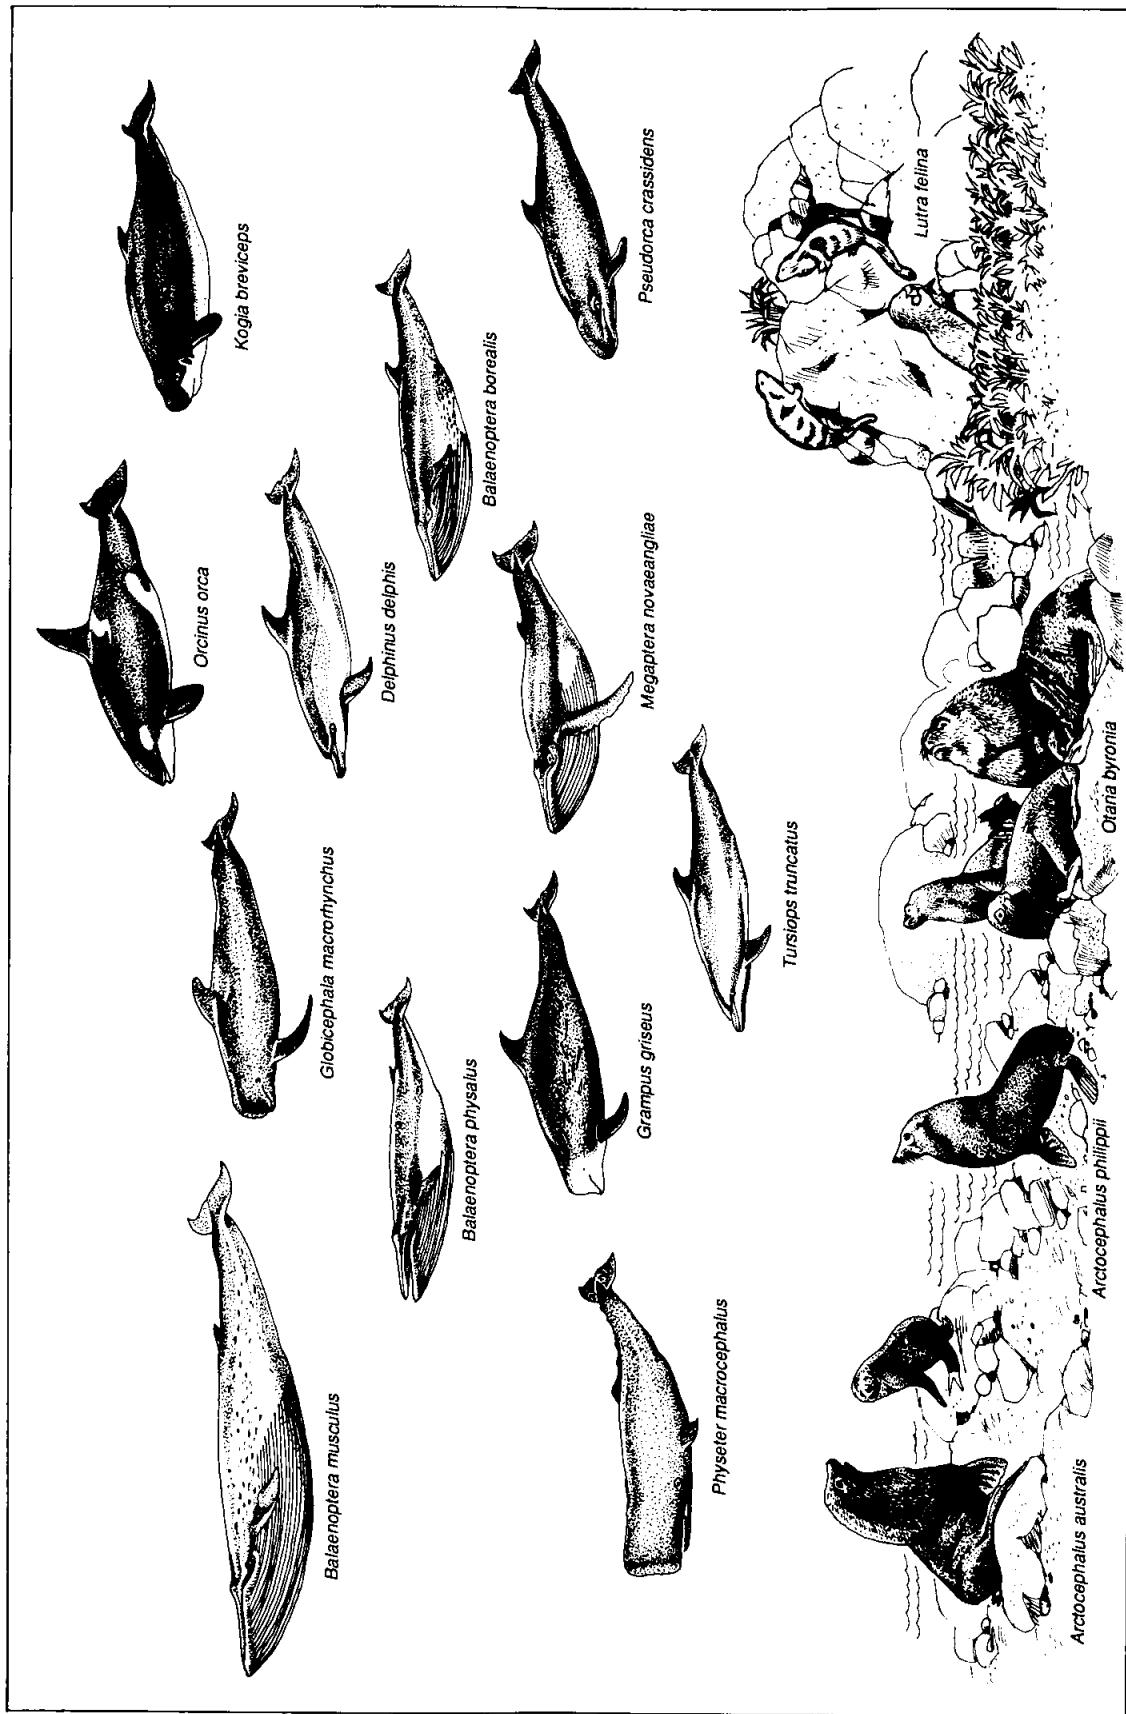

Fig. 2. Some of the species of marine mammals occurring off Peru. Adapted from drawings by Phil Schuyler (in Daugherty 1979), various photographs and drawings in King (1983) and Fig. 1 in Castilla (1982).

Fig. 2. Algunas de las especies de mamífero marino que se encuentra en aguas peruanas. Adaptado de los dibujos por Phil Schuyler (en Daugherty 1979), de varias fotografías y de dibujos en King (1983) y de la Fig. 1 en Castilla (1982).

Until 1979, over 90% of the fur seals in Peru were concentrated in three large colonies: Paracas (13°54'S), San Fernando (15°09'S) and Punta San Juan (15°22'S) (Majluf and Trillmich 1981). During the 1982-1983 El Niño, large numbers of fur seals migrated to colonies further south in Peru (Majluf 1985) or to northern Chile (Guerra and Torres 1987). The 1984 census shows that some previously smaller colonies in the south increased their numbers. South American fur seals are listed in Appendix II of the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES).

Breeding: fur seals are highly seasonal, polygynous breeders. In Peru, they reproduce between October and December with 90% of all births occurring during a period of about 40 days with a peak around 18-20 November. Females give birth to a single pup almost every year, but due to high mortality, only one out of every 3-4 pups survive to one year of age (see Majluf, this vol.). Pregnancy lasts 12 months and lactation may last up to 4 years. As a result of this extended lactation, females are often observed suckling more than one young simultaneously. Females mate for the first time when they are three years old (Majluf, unpub. data). Males may not reproduce until they are 6-8 years old.

Diet: The main food item for fur seals in Peru is adult anchoveta. They take other small pelagic schooling fish, but do so only when adult anchoveta availability is low (see Muck and Fuentes 1987; Majluf, this vol.). Young fur seals eat small benthic fish while they are learning to forage.

Fur seals feed almost exclusively at night following the vertical migrations of anchoveta (see Mathisen, this vol.). Variations in their prey distribution (increased depth or dispersion) cause female fur seals to lose weight because they have a lower foraging efficiency. This is reflected in an increase in pup mortality due to starvation (Majluf 1987; Muck and Fuentes 1987).

Interactions with fisheries: Fishermen in Peru always complain that seals take commercially valuable fish. However, even though adult fur seals do eat anchoveta, the biomass they take is negligible compared to that taken by the fisheries (see Muck and Fuentes 1987, and other contributions in Pauly and Tsukayama 1987a). Adults rarely eat the demersal fish which are most valued by the small-scale fishermen; young fur seals (1-3 years old) may be the only ones eating small benthic fish (P. Majluf, pers. obs.). As a result, they are commonly caught in demersal gill nets during their foraging attempts. Poaching of fur seals for their valuable skins is common everywhere in Peru.

Arctocephalus philippii Juan Fernandez fur seal (*Lobo fino de Juan Fernandez*)

Size: Juan Fernandez fur seals are slightly larger than South American fur seals. Standard length of adult males is 2.1 m (Torres 1987) and for females, 1.4 m (J. Francis, unpub. data). No weights are available for adult males; for females, average weight is 46 kg (J. Francis, unpub. data). Newborn pups measure about 65-70 cm and weigh 6-7 kg (Torres 1987).

Status and distribution: Juan Fernandez fur seals have never been reported on land outside the Juan Fernandez archipelago (33°80'S) and the San Felix and San Ambrosio Islands (26°80'S) off Chile (Torres 1987; Guerra and Torres 1987), where no more than 10,000 animals exist (Torres 1987). Juan Fernandez fur seals are listed in Appendix II of CITES.

From 1983, 10-15 adult or juvenile males (1-3 at any given time) have been observed hauling out in the South American fur seal rookeries at Punta San Juan every year mainly during the autumn and winter (Majluf, unpub. data). Mr. M. Rojo, a guard working at Punta San Juan between 1973 and 1984, reports having seen small mixed groups of Juan Fernandez fur seals at Punta San Juan (Marcial Rojo, pers. comm.). No females have been observed after 1983.

Because fur seals are all very similar, it is possible that more Juan Fernandez fur seals occur in Peru but remain undetected because observers do not notice the difference between them and the more common South American fur seal.

Breeding: Juan Fernandez fur seals exhibit similar breeding behavior to that of South American fur seals except for the lactation period, which rarely exceeds one year (D. Torres, pers. comm.). Juan Fernandez fur seals do not breed in Peru.

Feeding ecology: There is no information on the diet of Juan Fernandez fur seals in Peru. In Chile, they feed mainly on squid (Torres 1987).

Otaria byronia*
South American sea lion (*Lobo chusco*)

Size: South American sea lions are the largest otariids in Peru. Males may reach up to 400 kg and females 120 kg (Hamilton 1934). Newborns weigh 10-15 kg.

Status and distribution: Sea lions have, in South America, a distribution similar to that of fur seals. Their northern breeding limit in Peru is at Isla Foca in Piura ($5^{\circ}13'S$). They show a continuous and uniform distribution along the Peruvian coast (Majluf and Trillmich 1981).

The most recent estimate for the sea lion population in Peru is for 1984 when 33,000 individuals were counted (Tovar and Fuentes 1984). Since 1984, the population may have increased because of the exceptionally good environmental conditions in 1985 and 1987. Fishermen report dramatic increases in the rookeries south of $16^{\circ}S$.

Breeding: South American sea lions are polygynous, seasonal breeders. Females produce a single pup annually and may nurse it for one year and sometimes for a second year. The main breeding period for sea lions in Peru is between January and February but they have been observed pupping and mating throughout the rest of the year. In July, there is a secondary breeding period during which medium-sized males hold territories for 2-4 days and mate with very young, most probably virgin females (Majluf, unpub. data). No pupping is observed during this time.

Feeding ecology: Sea lions in Peru eat mostly small pelagic fish but are more opportunistic feeders than fur seals. They have been recorded taking anchoveta, horse mackerel (*Trachurus murphyi*) and sardines (*Sardinops sagax*). A detailed study of their diet is presently being carried out by Ing. Pedro Vasquez (Forestry Dept., Universidad Nacional Agraria, Lima) and should be completed in late 1989.

Interactions with fisheries: Sea lions are commonly observed taking fish from small-scale fishing gear and for this reason, they are regularly killed by fishermen when encountered at sea. There is no estimate of the damage by sea lion to the fisheries nor of the impact that the killing of sea lions by fishermen might have on the sea lion populations.

Cetaceans

Mysticeti: the baleen whales

Balaenoptera musculus
Blue whale (*Ballena azul*)

Size: The blue whales are the largest of all living mammals. They may reach up to 30 m in length and over 160 t (Leatherwood and Reeves 1983). Females are slightly larger than males. Newborns measure about 7 m long. Blue whales caught off Peru range between 12 and 24 m for males and 12 and 26 m for females (Ramírez 1983).

Status and distribution: Blue whales occur in all oceans, along ice fronts and the edge of continental shelves. They are also found in deep oceanic waters and shallow coastal regions. In the southern hemisphere, they spend the summer south of $40^{\circ}S$ and migrate northwards in the winter (Leatherwood and Reeves 1983; Mizroch et al. 1984). In Peru, blue whales can be sighted throughout the year but most often in the summer (Ramírez 1983). They are observed regularly north of Chimbote ($09^{\circ}04'S$) up to 200 miles offshore, where most whaling operations were carried out. There is no information on the distribution and abundance of this species south of these areas.

*Appears in many publications as *O. flavescens*. Oliva (1988) recently confirmed the taxonomic validity of *O. byronia*.

There are no recent estimates for the Peruvian blue whale population. A total of 644 and 622 blue whales were sighted in 1981 and 1982, respectively. Only 97 were sighted during the 1982-1983 El Niño (Ramírez and Urquiza 1985). The population is likely to consist of at least a few hundred individuals (Northridge 1984). Since 1965, blue whales have been protected by international agreement throughout most of the world; however, off Peru they were hunted until 1966.

Breeding: Blue whales show no well-defined social structure and most usually are observed singly, in pairs or in small groups. Mating occurs in the winter over a five-month long period. A single calf is produced every 2-3 years after a gestation period of about 12 months. Sexual maturity is reached by both sexes at about 5-15 years of age (Leatherwood and Reeves 1983; Mizroch et al. 1984).

Feeding ecology: Blue whales feed almost exclusively on euphausiids (krill), small crustaceans which tend to school close to the surface. A blue whale may consume up to 8 t of krill in one day. Most feeding occurs during summer; during winter, they fast, i.e., live off their fat reserves (Leatherwood and Reeves 1983).

Balaenoptera physalus
Fin whale (*Ballena de aleta*)

Size: The second largest whales. Adult fin whales may grow to about 27 m long in the southern hemisphere and, as all other rorquals, females are slightly larger than males. Calves are born measuring 6 to 6.5 m (Leatherwood and Reeves 1983). Until 1967, the mean length of animals caught off Peru was 13.6 m and afterwards 18.2 m. the longest was a female caught in 1971 measuring 23.4 m (Ramírez 1988a).

Status and distribution: Fin whales are also found in all oceans but are less common in tropical waters. They remain between 47 and 60°S during the summer and migrate northwards during the austral winter, going as far as Peru on the west coast of South America. Fin whale migration routes are not well known because they tend to travel in the open ocean instead of along coastlines (Leatherwood and Reeves 1983; Mizroch et al. 1984). Off northern Peru, they were sighted during whaling operations from September to April and less frequently throughout the rest of the year (Ramírez 1988a).

There are no estimates of abundance of fin whales in Peruvian waters. The stock for Peru and Chile has been estimated to be of no more than a few thousand animals (Northridge 1984). The catch of fin whales in the southern hemisphere was prohibited by the International Whaling Commission (IWC) in 1976 but catches off Peru continued through 1977.

Breeding: Fin whales are normally found singly or in small groups. They appear to have a biennial reproductive cycle. Mating takes place over a five-month period during the winter. Every 2-3 years, females produce a single large, precocial calf after a 12-month long pregnancy. Both sexes become sexually mature at 5-15 years of age (Leatherwood and Reeves 1983; Mizroch et al. 1984).

Feeding ecology: The main prey item of fin whales is krill. They feed only during the summer and fast during the winter. In the northern hemisphere, they may also feed on small pelagic schooling fishes (Leatherwood and Reeves 1983). A few fin whales have been observed eating krill off Paita but this is very rare. Most animals caught off Peru had empty stomachs (P. Ramírez, pers. comm.).

Balaenoptera edeni
Bryde's whale (*Ballena de Bryde*)

Size: Maximum body length for Bryde's whales is 14 m. Females are larger than males. Two distinct forms have been described for Peru: a coastal or "southern" form and an offshore or "northern" form (Valdivia et al. 1981; Ramírez and Urquiza 1985). Bryde's whales belonging to the coastal form are slightly smaller than those belonging to the oceanic form (mean length = 12.6 and 13.5 m, respectively; Valdivia et al. 1981).

Status and distribution: Concentrations of Bryde's whales are found in coastal areas of high productivity off Peru, Brazil, Venezuela, the Gulf of California, Japan and South Africa. Tropical populations may be sedentary but migration may occur in temperate populations (Leatherwood and Reeves 1983).

In Peru, the oceanic form is commonly found near Paita ($05^{\circ}05'S$) in the spring and summer, close to the coast between December and March (Valdivia et al. 1981). The coastal form is found further south, near Chimbote ($09^{\circ}04'S$), more often during the fall and winter but may also be seen during the rest of the year (Ramírez and Urquiza 1985). The latest estimates for the Peruvian stock of Bryde's whales range between 8,500 and 11,300 but these estimates have been criticized as too high (Northridge 1984). Bryde's whales were hunted off Peru until March 1985, when all Peruvian whaling activities finally stopped.

Breeding: Bryde's whales are usually observed singly or in small groups. They may also have a biennial breeding cycle. Mating and calving occur all through the year. Females produce a single calf every two years, after a gestation of about 12 months. Females attain sexual maturity at about 12.5 m and males at about 12.2 m (Leatherwood and Reeves 1983).

Feeding ecology: Bryde's whales appear to prefer small schooling fish throughout their range. In Peru, the coastal form feeds predominantly on sardines and other pelagic fish. The oceanic form feeds mainly on *Vinciguerra lucetia* and sardines. During the 1982-1983 El Niño, the coastal form also fed on horse mackerel and the oceanic form took euphasiids as well as *Vinciguerra* (Ramirez 1986). Feeding on anchoveta (*Engraulis ringens*) appears to be extremely rare, i.e., one case in three decades of sampling (P. Ramírez, pers. comm. to Pauly and Tsukayama 1987b).

Balaenoptera borealis Sei whale (*Ballena sei*)

Size: Males reach 17 m in length and females 21 m. Newborns are 4.5-4.8 m long (Leatherwood and Reeves 1983). Mean length for sei whales off Peru is 12.8 m (Ramírez 1988c).

Status and distribution: The distribution and movements of sei whales are very poorly known. This is partly because they are very difficult to distinguish from Bryde's whales in the field.

Like other baleen whales, they migrate to and from Antarctic waters, feeding at higher latitudes in the summer. They seem to prefer temperate and oceanic waters (Leatherwood and Reeves 1983). Off Peru, sei whales were caught in the northern whaling grounds. There is no information on their status in southern Peru. Sei whales are observed only between July and December (Ramírez 1988c).

There are no reliable estimates for the sei whale population off Peru but there might be a few thousand (Northridge 1984).

Breeding: Sei whales usually occur in groups of 2-5 individuals but may concentrate in larger groups in the feeding grounds. The gestation period lasts about 12 months, the females attain sexual maturity at ten years of age (at six in heavily exploited areas) and may reproduce every 2-3 years (Leatherwood and Reeves 1983).

Feeding ecology: The diet of sei whales consists mainly of krill and small schooling fish. Feeding in this species also occurs almost exclusively in the summer in the Antarctic, but off Peru, they have occasionally been observed eating krill (P. Ramírez, pers. comm.).

Megaptera novaeangliae Humpback whale (*Ballena jorobada*)

Size: Female humpback whales are slightly larger than males. Adult females may reach up to 16 m and males up to 15 m long (Leatherwood and Reeves 1983). Off Peru, however, a male measuring 17.5 m has been reported (Ramírez 1988b). Mean length for female humpbacks off Peru is 12.4 m and for males, 12.0 m (Ramírez 1988b). Newborns are 4-4.5 m long (Leatherwood and Reeves 1983).

Status and distribution: Humpback whales may be found in all oceans. They undergo extensive annual migrations along well-defined routes. In the southern hemisphere, most humpbacks spend the summer in Antarctic waters and migrate northward towards the equator in the winter (Leatherwood and Reeves 1983; Johnson and Wolman 1984). In Peru, they are observed in the whaling grounds between May and December but more frequently between September and November (Ramírez 1988b). There are no population estimates for humpbacks off Peru, but they probably do not exceed a few hundred (Northridge 1984).

Humpback whale stocks in the southern hemisphere have been protected since 1964; however, Peru continued hunting this species until 1966.

Breeding: Humpbacks are usually found alone or in groups of 2-3 individuals but may form larger groups (up to 15) in breeding or feeding areas. Females reproduce every two or more years but are able to do so annually. The gestation period lasts 12 months (Leatherwood and Reeves 1983; Johnson and Wolman 1984).

Feeding ecology: Humpback whales feed in summer on krill and schooling fish and fast in winter, as do most other baleen whales. There is no information on their feeding habits off Peru.

Interactions with fisheries: Off Peru, humpbacks tend to occur close to shore in the spring (Ramírez 1988b), making themselves vulnerable to entanglement in fishing gears. There is a single record of entanglement of a humpback whale at Punta San Juan in October 1988. The whale was released alive and the fishermen were partially compensated for the damage to their nets^a.

Odontoceti: the toothed whales, dolphins and porpoises

Physeter macrocephalus Sperm whale (*Cachalote*)

Size: Sperm whales are highly sexually dimorphic with males being much larger than females. Adult males may attain 18 m in length although at present, due to intense exploitation of large males, few exceed 15 m. Females rarely reach 12 m in length. Newborns weigh one tonne and are 3.5-4.5 m long (Leatherwood and Reeves 1983; Gosho et al. 1984).

Status and distribution: This species is found in all oceans between 60°N and 70°S in very deep waters and only rarely in waters less than 180 m deep. Off Peru, the highest concentrations are found around Pisco and Paita, the grounds of past whaling days. The highest concentrations off Pisco occur in the winter and for Paita, in the spring and summer. These differences suggest a seasonal migration between these two areas (Saetersdal et al. 1963). There is no information on their distribution south of Pisco but they are regularly sighted north of Punta San Juan and in Ilo in the spring.

There are no reliable estimates for the sperm whale population off Peru but it may be in the tens of thousands (Northridge 1984).

Breeding: Sperm whales have a polygynous breeding system. Although often seen singly or in small groups, they may form large groups of up to several hundreds. The largest groups are observed during the breeding season. Groups can be mixed (breeding schools) or consist of only young males (bachelors' schools). Large adult males are usually solitary but join the breeding schools during the breeding season (Leatherwood and Reeves 1983; Gosho et al. 1984).

Mature females in the southern hemisphere ovulate between October and February and produce a calf every 3-6 years, after a 15-month long gestation. Lactation lasts 1-2 years. Females attain sexual maturity at about 9 years when they are about 9 m long and males at about 20 years and 12 m long (Leatherwood and Reeves 1983; Gosho et al. 1984).

Some aspects of the reproductive behavior of sperm whales off Peru have been described by Ramirez (1988d).

Feeding ecology: Sperm whales feed primarily on squid but may also eat octopus and fish. The main prey species for sperm whales in Peru is the jumbo flying squid (*Dosidiscus gigas*) which occurs in very high densities in Peruvian waters. According to Clarke et al. (1968), the high abundance of sperm whales in Peru may be related to the high concentrations of squid in the Peruvian upwelling system.

^aBy the senior author (Editors' note)

Phocoena spinipinnis
Burmeister's porpoise (*Marsopa espinosa*)

Size: Maximum length is about 1.8 m (Reyes et al. 1988). Males and females appear to be similar in size.

Status and distribution: Temperate and coastal waters of South America. On the Pacific coast, Burmeister's porpoise occurs from Paita, Peru, south to Valdivia, Chile. On the Atlantic coast, it ranges from Punta del Diablo (Uruguay) to Golfo San Jose (Argentina). The distribution of this porpoise in southern South America is poorly known (Brownell and Praderi 1984).

Brownell and Praderi (1982) suggest the existence of two separate stocks, the Atlantic and the Pacific stocks, with probably the Pacific stock being the larger of the two. They describe this species as the most abundant small cetacean in coastal waters around southern South America and that about 2,000 are caught by fishermen off Peru every year. There are no estimates of abundance for this species in Peru.

Breeding: Burmeister's porpoise usually occurs in groups of up to six or eight animals. There is no information available on the breeding ecology of this species (Leatherwood and Reeves 1983).

Feeding ecology: This is an inshore species which preys on a variety of pelagic and demersal fishes, especially anchoveta, drum (*Sciaena deliciosa*) and hake (*Merluccius gayi*) as well as squids such as Patagonian squid (*Loligo gahi*) (McKinnon 1988).

Interactions with fisheries: Burmeister's porpoises are captured incidentally in the gill net fishery along its range (Brownell and Praderi 1984). The demersal gill-net fishery for sharks accounts for a relatively high number of these porpoises taken in Peruvian waters (Read et al. 1988).

Lagenorhynchus obscurus
Dusky dolphin (*Delfin oscuro*)

Size: Maximum length is 2.1 m, weight = 136 kg. Males are slightly larger than females (Leatherwood and Reeves 1983).

Status and distribution: Circumpolar distribution in warm temperate and cold temperate waters of the southern hemisphere (Leatherwood and Reeves 1983). Along the Peruvian coast, it has been recorded between Huacho (Brownell 1974) and Atico (Bini 1951). No population size estimates exist for this species.

Breeding: In the S. Atlantic herds of 5 to 30 are common, but groups may reach several hundred. Group size seems to vary seasonally (Würsig and Würsig 1980). Data from New Zealand show a gestation of 9-11 months with calves born in mid-winter. Lactation lasts for 18 months. Off Argentina, young are born in the summer (Leatherwood and Reeves 1983).

Feeding ecology: Dusky dolphins are known to feed on fishes, primarily anchovies, and squids (Leatherwood and Reeves 1983). In Peruvian waters, anchoveta is the main food, while horse mackerel, hake and Patagonian squid are eaten in smaller proportions (McKinnon 1988).

Interactions with fisheries: In Peru, dusky dolphins are taken both incidentally and directly by fishermen. The bulk of these catches occurs in the small-scale fishery off Central Peru, where gill nets, harpoons and purse seines are used. About 1,500 of these dolphins were taken in two Peruvian ports in 1985 (Read et al. 1988).

Delphinus delphis
Common dolphin (*Delfin comun*)

Size: Maximum length = 2.5 m, with males slightly larger than females. Weight = not more than 75 kg. Newborns are about 80 cm long (Leatherwood and Reeves 1983).

Status and distribution: Cosmopolitan, absent only from high latitudes. In the South Pacific, there are records from the equator to 40°S off Chile, on the Pacific coast of South America. There are no population estimates for this species.

Breeding: Herds of over a thousand are not uncommon but groups numbering many hundreds are the rule. Gestation lasts 10-12 months. Calving interval is about 1.3 years. In the north Pacific, calving appears to peak in spring and fall. Sexual maturity is reached at 3 to 4 years (Leatherwood and Reeves 1983; Minasian et al. 1984). There is no information on breeding in Peru.

Feeding ecology: Common dolphins are primarily pelagic, commonly found above depths of 200 m, but inshore forms occur in some areas. There appears to be a daily cycle of activity related to the movements of the organisms associated with the deep scattering layer. Common dolphins prey on small pelagic fishes such as anchovies, lanternfish, sardine and herring, as well as squid. There is no available information on the feeding habits of these dolphins off Peru.

Interactions with fisheries: Common dolphins are taken in the small-scale fishery along the Peruvian coast either with nets or harpoons. Some catches also occur in the industrial purse seine fishery, especially off the central Peruvian coast (Read et al. 1988; Van Waerebeek and Reyes 1988).

Tursiops truncatus
Bottlenose dolphin (*Delfin pico de botella*)

Size: Maximum recorded length is 3.9 m; weight, 275 kg. Males are larger than females. Length at birth is about 0.9-1.2 m (Leatherwood and Reeves 1983; Reyes et al. 1988).

Status and distribution: This species is cosmopolitan in all temperate, subtropical and tropical waters, and is present all along the coast of Peru. An inshore form and an offshore form have been described for this species in Peruvian waters (Van Waerebeek et al., in press). The offshore form inhabits the tropical waters outside the coastal upwelling zone and is known to range as far south as 13°S (Walker 1981; Donovan 1984). The inshore form is restricted to the shallow waters along the coast and has been reported from Mancora in northern Peru (Grimwood 1969) to Concepcion, Chile (37°S) (Oliver 1946). There are no estimates for the size of the Peruvian population of bottlenose dolphins.

Breeding: Inshore bottlenose dolphins swim in groups of ten or less. Group size in the offshore form is about 25 but herds of several hundred may occur (Leatherwood and Reeves 1983). Sexual maturity is reached at 10-12 years in males and 5-12 years in females. Gestation lasts 12-18 months. The life span is believed to be about 35 years (Leatherwood and Reeves 1983; Minasian et al. 1984).

Feeding ecology: The inshore form preys on a variety of fish including mullets and sciaenids, while offshore dolphins have been reported to feed mainly on oceanic squid (Walker 1981). In Peruvian waters, bottlenose dolphins identified as belonging to the inshore form eat anchoveta, drums, mullets, hake and Patagonian squid. Several types of squid beaks, some of them from jumbo flying squids, are common in the stomachs of offshore bottlenose dolphins, along with some fish species (Van Waerebeek et al., in press).

Interactions with fisheries: Incidental and direct catches occur throughout the species' range (Leatherwood and Reeves 1983). A small number is taken each year in the small-scale fishery off Peru, although greater numbers are captured by the industrial fleet in some of the larger Peruvian ports (Read et al. 1988; Van Waerebeek et al., in press). Offshore dolphins are captured mainly during the summer months when the width of the coastal upwelling zone is reduced and the fishermen are able to reach tropical offshore waters (Van Waerebeek et al., in press).

Globicephala macrorhynchus
Short-finned pilot whale (*Ballena piloto de aleta corta*)

Size: Males reach 5.4 m and 3,000 kg; females are 4 m long with an estimated weight of 1,200 kg. Length at birth is about 1.4 m (Leatherwood and Reeves 1983; Minasian et al. 1984).

Status and distribution: Tropical and warm temperate waters of the Pacific, Atlantic and Indian oceans. This species was only recently identified in Peruvian waters (Van Waerebeek and Reyes 1986) and thus, there is only limited information on its distribution and no population estimates are available. The population of the eastern tropical Pacific has been estimated as 60,000 (Leatherwood and Reeves 1983).

Breeding: Group size ranges from a few to several hundred. Males become sexually mature when they are 4.2-4.8 m in length; females mature at 3-3.3 m. The breeding season appears to be extended, while the gestation period is about 11-13 months. Calving interval is approximately 3 years (Leatherwood and Reeves 1983; Minasian et al. 1984). Lactation lasts a minimum of 2 years, although it may continue for considerably longer periods (Kasuya and Marsh 1984).

Feeding ecology: Short-finned pilot whales are found mainly in offshore waters, but they seem to migrate to inshore waters following the squid which are their main food (Leatherwood and Reeves 1983).

Interactions with fisheries: Gill net and commercial purse seine fisheries off Peru take a few short-finned pilot whales every year (Van Waerebeek and Reyes 1986; Read et al. 1988).

Orcinus orca Killer whale, Orca (*Orca*)

Size: Males may reach up to 9.5 m and around 8,000 kg; females rarely exceed 7 m in length and 4,000 kg in weight. Length at birth is about 2.1-2.4 m (Leatherwood and Reeves 1983).

Status and distribution: Cosmopolitan. In Peru they have been reported around Chançay (11°22'S, Bini 1951) and around northern Peru by Dahlheim et al. (1982). In southern Peru in recent years they have been sighted close to the coast mainly in winter (July-September) around Punta San Juan (P. Llerena, pers. comm. and P. Majluf, pers. obs.), Paracas and Ilo (J.C. Riveros, pers. comm.). There are no estimates of abundance for this species in Peru.

Breeding: Moderately gregarious, polygynous. They form stable groups (pods) varying in size reaching up to 30 individuals and containing adults of both sexes as well as calves and juveniles. Sometimes pods form short-term aggregations of a hundred or more individuals (Leatherwood and Reeves 1983). In Peru they have been sighted in pairs and small groups (3-4 animals). There are no data on the composition of these groups.

Little is known of the breeding biology of this species. Females may give birth every two years or more. Gestation lasts for at least a year and perhaps several months longer. Calves are born around August to March and may remain dependent on their mothers for at least a year (Leatherwood and Reeves 1983; Bigg et al. 1987). A single birth was reported off Punta San Juan in 1988, but this has not been confirmed (P. Llerena, pers. comm.).

Feeding ecology: According to Leatherwood and Reeves (1983), "There seems to be no palatable marine organism of any size that is safe from attack". They have been observed feeding on virtually all species of oceanic cetaceans (including their own kind), pinnipeds, penguins, many kinds of seabirds, sea turtles and fish. In Peru they have been observed feeding on both fur seals and sea lions off Punta San Juan. On a single day they were estimated to eat at least 50 young (0-2 year old) sea lions. Adults were also taken occasionally. Hunting occurred singly or in pairs (R. Harcourt, pers. comm. and P. Majluf, pers. obs.).

Interactions with fisheries: There is a single report of an orca having been caught by fishermen off Pucusana (Cesar Cárcamo, pers. comm.). Around Punta San Juan, fishermen observe orcas regularly but do not report interactions.

Otters

Lutra felina Marine otter (*Chungungo, gato marino*)

Size: Maximum length, 1.0 m (Cabello 1983). Average weight, 4.0 kg (IUCN 1982). Males and females appear to be similar in size.

Status and distribution: Marine otters are found along the coasts of Peru and Chile from 9 to 56°S (Brack 1978; Cabello 1983). They are mainly found in rocky shores but there are reports of occurrences in rivers and streams not altered by fisheries for crayfish (Hvidberg-Hansen 1970).

The status of marine otter in Chile was discussed by Castilla (1981, 1982). There are, on the other hand, no reliable population estimates for the species in Peru. In some relatively

undisturbed areas such as Isla San Gallan ($13^{\circ}49'S$), Punta La Chira ($16^{\circ}31'S$) and Morro Sama ($18^{\circ}00'S$), there is approximately one otter per 100 m of shoreline (J.C. Riveros, unpub. data). This estimate is similar to that of Cabello (1983) for Chiloe Island ($42^{\circ}10'S$) in Chile. Fishermen report a decrease in the otter population in recent years.

Marine otters are listed in Appendix I of CITES and are included as vulnerable in the IUCN Red List of Threatened Animals (1986). In Peru, legal protection is limited to a short season when hunting is prohibited between 15 December and the end of January. This regulation appears unknown to fishermen along the Peruvian coast.

Breeding: Marine otters occur singly or in family groups. The young are born in burrows onshore during the austral spring (Sielfeld 1983). Gestation lasts 60-65 days and there are 1-2 young per litter (Estes 1986).

Feeding ecology: There are no detailed studies of the diet of this species in Peru. Preliminary analysis of scats by Riveros and Hays (unpubl. data) suggested that they mainly feed on reef-dwelling fish, small crabs and *Tegula* snails, while fishermen report them feeding on freshwater prawns (*Cryphioptes caementarius*) (Hvidberg-Hensen 1970). A comprehensive study by Castilla and Bahamondes (1979) showed a Chilean population to feed on marine invertebrates, especially *Concholepas concholepas* and *Fissurella* spp.

Interactions with fisheries: In Peru, marine otters are killed occasionally by fishermen for their fur and meat and sold as stuffed animals (Hvidberg-Hensen 1970). There appears to be no conflict with the fisheries. Shellfish fishermen are seen commonly working next to otters (J.C. Riveros, pers. comm.). However, in Pucusana ($12^{\circ}30'S$) and Punta San Juan, there are reports of otters becoming entangled and drowned in gill nets (J.C. Reyes, pers. obs., and P. Llerena, pers. comm.).

History of Exploitation

The Seals

The use of seals in Peru dates as far back as preceramic times (>5,000 BC). Large numbers of fur seal and sea lion remains have been found in archaeological diggings along the entire coast of Peru (Bonavia 1982). Seals were taken together with guano birds (*Phalacrocorax bougainvillii*, *Sula variegata* and *Pelecanus thagus*) and various species of pelagic fish. Wing and Reitz (1982) have calculated, using estimates of the biomass of different species consumed by humans, that the two seal species constituted the major component of the diet of coastal Peruvians in pre-ceramic times (Wing and Reitz 1982).

In pre-Hispanic times, seals appear to have been hunted on a regular basis for their meat, oil and skins. Inflated skins may have also been used as floats (Cobo 1956). The Mochicas left numerous representations of seals and the seal hunt in their ceramics (Bonavia 1982). López de Gomara (1941) and Gutiérrez de Santa Clara (1905) both describe seals being baked and eaten and their oil being used for different purposes up to the 16th century. By the first half of the 18th century, seals were only taken for their oil (Cobo 1956).

Large-scale commercial exploitation of seals may not have started until the 18th century when sperm whalers, in search of new whaling grounds, killed millions of fur seals (*Arctocephalus* spp.) and depleted most southern hemisphere fur seal populations (Bonner 1981). Unfortunately, there are no records of the numbers of seals taken off Peru before 1925. From then on, there are yearly export figures given in "tonnes of skin^b" for the period 1925-1946. Presumably, more than one company was involved in the seal hunt and the export figures include only those skins legally exported. To interpret these figures, we can use the following example: between December 1941 and March 1942, a single company collected 36,650 skins (32,400 pups, 3,700 adult females and 550 adult males) (Piazza 1969), while 10,400 "tonnes of skin" were reported (for all companies). If we assume that these skins were mainly those of sea lion^c pups with live weights of 30-40 kg at the most and that hence, the skins may not weigh more than 2-3 kg a piece, then in 1942 alone, several thousand pups were killed to make up 10,400 "tonnes of skin" and several million more were killed to complete the 806,252 "tonnes of skin" exported between 1925 and 1946.

^bNo indication of species is given nor is it clear whether "skin" included blubber as well. Here, we assume "1 tonne of skin" = 1,000 kg of skin without blubber.

Under this intense exploitation, the seal population was so rapidly depleted that it had to be granted partial protection in 1946. That year, the Peruvian government limited the seal hunt to the period between 1 January and 15 March and prohibited the killing of young pups. In 1950, protection was extended to adult female sea lions and to all fur seals. In 1958, all seal hunting was banned (Tovar and Fuentes 1984). By June 1967, however, "experimental" exploitation of seals was again allowed even though the populations had not recovered. No records of the hunt after 1946 are available.

Between 1971 and 1975, under the auspices of the military government, Empresa Peruana de Servicios Pesqueros (EPSEP) took 12,699 sea lions and 4,188 fur seals (Table 2), a high proportion of the total population in each year (over 20% in 1974). This excessive catch must certainly have had a negative effect on the population. In 1975, only sea lions were taken. In 1976, all hunting of seals was again prohibited (Tovar and Fuentes 1984).

Since then, seals in Peru have been legally protected but due to a complete lack of coastguards, poaching at sea and in isolated rookeries has taken place on a regular basis. Fishermen shoot or harpoon seals which approach their boats, claim damage to their fishing gear and demand permission again to hunt seals legally. So far, these claims and demands have been ignored by the Peruvian government.

The Large Whales

Large cetaceans apparently were not hunted in Peru until the 18th century when North American sperm whalers traveling to and from the Antarctic discovered the rich whaling grounds off central and northern Peru. Previously, only the remains of stranded whales were used opportunistically. In preceramic times, ribs and other large bones were used as building material instead of wood which is a scarce resource in coastal Peru (Bonavia 1982). Large vertebrae were also used as bases for grinding stones (D. Bonavia, pers. comm.).

Cobo (1956), a priest describing Peru in the early 17th century, also mentioned that whales were not hunted by the coastal people and that only stranded animals were used for various purposes. However, both Vasquez de Espinoza (1948) and Lopez de Gomara (1941) describe Indians in northern Peru and in the Atacama desert in Chile hunting whales using copper harpoons. In general, there is very little information on the early exploitation of large whales in Peru in the 16th-19th centuries. As mentioned above, whale hunting in Peruvian waters was started by North American whalers on their way to and from the Antarctic. These were soon followed by British and Norwegian whalers attracted by the abundance of sperm whales in these waters (Hertz and Kapel 1986). These early whalers used sail vessels and could only catch sperm whales and the slow swimming humpback whales. Townsend (1935) describes sperm whales being hunted at all seasons of the year off Peru, Ecuador and Chile between 1761 and 1920. Humpbacks only rarely were caught off Peru and Chile but were caught in great numbers in Ecuadorian waters.

^cThe fur seal population in Peru was at very low levels throughout the first half of the 20th century (see above).

Modern whaling, using steam vessels and harpoon guns, did not start in Peru until 1925-1926 (Clarke 1962). This allowed whalers to hunt the faster swimming species (blue, fin, sei and Bryde's whales) but sperm whales were still their main target.

The catch numbers and composition early in this century is poorly documented. Detailed numbers and species composition of the catch are only available from 1936 (Table 3). Whaling off Peruvian waters in the first half of the 20th century was mainly offshore and carried out intermittently. The main expeditions took place in 1936-1938, 1941-1943, 1947-1948, 1951 and 1954. Shore-based whaling in Peru did not start until 1951 (Clarke 1962). Baleen whales were caught intermittently between 1936-1937, 1947-1956, and from 1959 onwards. Between 1953

and 1966, there were attempts to introduce whale meat for human consumption (Ramírez 1988a, 1988b) and the last blue and humpback whales were caught for this purpose. Hunting of blue and humpback whales was banned by the IWC in 1966. Fin whales were also protected by the IWC in 1966 but were hunted in Peru until 1977.

The catches of sperm whales off Peru were very large and during the early years of this century, contributed up to 20-60% of the worldwide catch (Fig. 3). Due to their greater size and their spermaceti, the larger males were preferred and thus, only few females were caught before 1951. This preference was reflected soon in a decrease in availability of large males which caused whalers to catch a greater proportion of females after 1951 (Saetersdal et al. 1963).

Between 1954 and 1961, there was a noticeable decrease in catch per unit effort (Saetersdal et al. 1963) but catches did not decline until 1965. From then and until 1982, when hunting of the species was banned by the IWC, catches did not exceed 2,000 animals per year (Ramírez 1989).

Bryde's whales were the last species to be hunted in Peruvian waters. When most other countries in the world had agreed to stop whaling, Peru, Japan, the USSR, Norway and Iceland continued. The company running the whaling operations in Peru was Japanese-owned and most of the whale meat was exported to Japan. However, due to international pressure and after it was shown that there was no market for whale meat in Peru, all whaling operations were finally stopped in Peru in 1985.

The Dolphins and Porpoises

Little is known of the use of dolphins by ancient Peruvians. Dolphin remains have not been found in preceramic sites (D. Bonavia, pers. comm.). The Nazcas left multiple representations of orcas on ceramics (Proulx 1983), but no bones of this species have been found in diggings (D. Bonavia, pers. comm.). There is no information on the history of exploitation of small cetaceans in Peru prior to 1962. In this year, Clarke (1962) reported that Burmeister's porpoises were sold every day in the port of Chimbote. Grimwood (1969) reports that dolphins and porpoises were frequently caught by small boat fishermen in ports such as San Andres and others. He wrote "...the price they fetch, however, is so low compared to that obtained for fish that it is doubtful if they are fished for deliberately." Subsequently, Clarke et al. (1978) report observing porpoises in the markets of Chimbote, Ancon, Callao, Pucusana, San Andres and Ilo in 1971-1972.

The first estimate of the magnitude of the catch of small cetaceans in Peru were from Mitchell (1975) who based his estimates on information provided by the Instituto del Mar del Peru (IMARPE) and on unpublished data from K.S. Norris. According to his report, about 1,000 tonnes of porpoises were sold in fish markets every year, mainly Burmeister's porpoises, and a small number of dusky dolphins. At least 2,000 small cetaceans were reportedly taken incidentally in gill nets set for sciaenids (Brownell and Praderi 1982).

Recent studies have revealed that several species of small cetaceans currently are taken along the Peruvian coast, with higher numbers being taken off the central coast (Read et al. 1988). The development of this fishery seems to have originated after the collapse of the anchoveta fishery in the early 1970s. The most exploited species is the dusky dolphin, for which

a directed gill-net fishery exists, but bottlenose dolphins are also taken regularly. Small cetaceans are caught incidentally in gill nets set for sharks, and directly with gill nets and hand-thrown harpoons. Catches also occur in the industrial purse-seine operations for pelagic fishes. Approximately 10,000 animals were caught in 1985 by the fisheries, the meat being used for human consumption (Read et al. 1988). A dramatic increase in the small cetacean fisheries in recent years has been shown by Van Waerebeek and Reyes (1988) and has been linked to a worsening of the economic situation in Peru. At present, there is no legal protection for small cetaceans in Peru.

Discussion

The studies carried out in recent years have led to a better understanding of the seal and small cetacean populations in Peru. However, what we know about them is still very limited and not sufficient to design a conservation strategy for any of these species. Some of these are known from only a few specimens stranded on beaches and for most, we have only details of their anatomy and/or ecology. For the large cetaceans, the information available covers only the main whaling areas in northern Peru, while nothing is known about their distribution and abundance in the south of the country. Because commercial fisheries in Peru are aimed mainly at small pelagic fish, the major prey of most marine mammals, conflict is always likely. Also, marine mammals are highly valued for their skins, oil, and meat and thus, with the present economic crisis in Peru, the impoverished fishermen are even more likely to hunt these animals, legally or not, to supplement their incomes.

Management of the fisheries for marine mammals has always been deficient. Quotas for the exploitation of whales were based on dubious estimates of abundance in Peruvian waters. Seals were hunted intensively without their numbers being known and based on estimates of breeding success from related species now known to have much higher pup production. Small cetaceans are still hunted in very high numbers without any population estimates. Both seals and small cetaceans are particularly vulnerable during their reproductive periods, when they are close to the land. Many species of dolphins and small whales are only available to the fisheries during the summer, when the Humboldt current is narrower and fishermen can reach oceanic waters close to the coast (Read et al. 1988). Fortunately, at present, the exploitation of large whales has been banned internationally and it is no longer carried out in Peru. However, some large cetaceans, for example humpback whales, also approach the coast in the spring and are likely to get entangled in gill nets.

Human activities also have an indirect effect on marine mammal populations in Peru. Overexploitation of pelagic species of fish reduced the food base of marine mammals. Once very abundant in Peruvian waters, the anchoveta population collapsed in the early 1970s and has not recovered since (see contributions in Pauly and Tsukayama 1987a and other contributions in this vol.). This resource used to sustain large populations of marine mammals off Peru. Recovery of these marine mammal populations to their former levels is therefore unlikely, since the biomass of anchoveta necessary to maintain large numbers of sea mammals is no longer available.

Marine mammal populations in Peru are not only affected by human activities. Being the top predators in the marine ecosystem, natural changes in prey availability also affect their breeding success and survival. During El Niño events, anchoveta migrate to deeper waters or disperse (Arntz 1986) and so fur seal females have to spend more energy for foraging (see Majluf, this vol.). Particularly, they must dive to great depths more frequently than in "normal" years and the prey they obtain is of lower energy content. As a result, they are not able to cover the energy demands of lactation and their pups starve or have reduced growth. Adults may also be affected if the intensity of the event is high (Majluf 1987). Similar effects of El Niño events have been described for sea lions (Limberger et al. 1983). Small cetaceans can be assumed to be affected in an analogous fashion. Bryde's whales feeding off Peruvian waters were found to have empty stomachs more often during El Niño events than in years without such events (Ramírez and Urquiza 1985). There is no information on the effect of decreased foraging success on whale reproductive output, but it is likely to be negative. Thus, even though living in the rich Peruvian upwelling system allows marine mammals access to abundant food resources, they also have to endure unpredictable variations in their food supply, which makes them, in poor years, even

more vulnerable to human predation. Although we now have a better understanding of some of the natural factors affecting the marine mammals in Peru and of their interaction with fisheries, we still need detailed information on their life history, distribution and survival before we can design adequate conservation/management policies.

Also, Peruvian marine mammals have been exploited only as fisheries resource. Alternative uses, such as for tourism (seal and whale-watching) have not been considered. The tourist potential of areas such as the Paracas National Reserve and Punta San Juan, where large numbers of fur seals and sea lions are readily accessible and where dolphins, whales and otters are regularly observed, should be assessed. In other South American countries, for example Argentina, Chile and Mexico, there are numerous areas where whale and/or seal watching has replaced direct harvesting and are currently generating substantial revenues (Barstow 1986).

There is a history of overexploitation of all fisheries resources in Peruvian waters and marine mammals are no exception. Nonconsumptive utilization of marine mammals as a tourist attraction not only is an effective means of conservation of these animals through direct protection and increased public awareness of these animals, but also has the potential to continue to generate revenue in the long term. There is already a large tourist industry in Peru, and therefore, it should be relatively straightforward to add whale- and seal-watching trips to tours of this country. However, tourism has the potential to cause harm to marine mammals, e.g., through disturbance at mating sites (Barstow 1986) and it is important that care be taken in designing and implementing any tourist scheme. Considering the depressed economic climate in Peru, and the relatively poor return from the marine mammal fishery, nonconsumptive use is a potentially attractive option which should not be ignored.

Acknowledgements

We are grateful to the Peruvian Ministry of Fisheries and to two government agencies (PESCAPERU and EPSEP) for their logistic support and access to unpublished data. The small cetacean studies were carried out jointly with Koen Van Waerebeek (University of Gent), Andrew Read and Jeff McKinnon (University of Guelph). Many thanks to them for allowing use of unpublished data. Anthony Luscombe (ECCO) helped these studies with logistic support and specimen collection. Drs. Pedro Ramírez (IMARPE), Duccio Bonavia (U.P. Cayetano Heredia) and Robert Clarke kindly allowed access to their libraries and gave many useful comments. We are also grateful to Dr. John Francis (NZP - Smithsonian Inst.), Juan Carlos Riveros (APEC) and Pedro Llerena for providing unpublished data on *A. philippii* and *L. felina*. To Robert Harcourt (University of Cambridge) and K. Van Waerebeek, many thanks for their multiple revisions of the manuscript and constructive criticisms.

Pinniped research was funded by grants from Wildlife Conservation International (a division of the New York Zoological Society) to Patricia Majluf. Small cetacean research was partially funded by the IUCN/UNEP Burmeister's Porpoise Project, supervised by Dr. David Gaskin (University of Guelph), the Leopold III - Fonds voor Natuuronderzoek en Natuurbehoud (Belgium) and the Natural Sciences and Engineering Research Council (Canada).

MENDELSSOHN, R. 1989. A reanalysis of recruitment estimates of the Peruvian anchoveta in relationship to other population parameters and the surrounding environment, p. 364-385. In D. Pauly, P. Muck, J. Mendo and I. Tsukayama (eds.) *The Peruvian upwelling ecosystem: dynamics and interactions*. ICLARM Conference Proceedings 18, 438 p. Instituto del Mar del Perú (IMARPE), Callao, Perú; Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ) GmbH, Eschborn, Federal Republic of Germany; and International Center for Living Aquatic Resources Management (ICLARM), Manila, Philippines.

Abstract

New recruitment estimates of the Peruvian anchoveta are analysed with respect to other population parameters and the surrounding ocean environment. The inshore and offshore environmental variables differ in their dynamics, and the inshore series vary north to south. For the inshore locations, it is not possible to resolve if a wind-related effect is due to transport or turbulence. The new recruitment estimates differ significantly from the old estimates, partly due to mackerel consumption acting as a surrogate for SST. Models using the monthly data were not possible due to correlations in the populations that could be spurious. On a yearly basis, a nonlinear additive model using parent biomass and transport at Trujillo explained 75% of the variance in the recruitment estimates.

Resumen

Nuevos estimados de reclutamiento de la anchoveta peruana se analizan en relación con otros parámetros poblacionales y el ambiente en que habita. Las variables ambientales costeras y distantes de la costa difieren en su dinámica, y las series costeras varían de norte a sur. Para las localidades costeras, no es posible establecer si un efecto relacionado con el viento es ocasionado por el transporte o la turbulencia. Los nuevos estimados de reclutamiento difieren significativamente de los estimados antiguos, debido parcialmente al consumo del jurel que actúa como un indicador de la temperatura. No ha sido posible aplicar modelos que utilizan datos mensuales debido a que las correlaciones en la población pudieran ser espurias. Un modelo aditivo no lineal usando la biomasa parental y el transporte de Trujillo, sobre una base anual, explica el 75% de la variancia de los estimados del reclutamiento.

Introduction

One of the main goals of the contributions in Pauly and Tsukayama (1987) was to estimate the demographic parameters of the Peruvian anchoveta, taking into account all sources of mortality. Thus, estimates of anchoveta consumption by birds (Muck and Pauly 1987), marine mammals (Muck and Fuentes 1987) and bonito (Pauly et al. 1987) were included in the estimation algorithms. Muck and Sanchez (1987), however, presented evidence that mackerel and horse mackerel are major predators of the anchoveta, with consumptions levels approaching that of the fishery at its highest levels. As the mackerel consumption was not included in the original estimates, new population estimates have been calculated (Pauly and Palomares, this vol.).

These new population estimates, as well as the corrected alongshore stress series in Bakun and Mendelsohn (this vol.), are the impetus for redoing the analysis in Mendelsohn and Mendo (1987, hereafter referred to as M&M). Besides examining some models for using population and

environmental parameters to forecast the new estimates of anchoveta recruitment, this reanalysis affords me the opportunity to delve in more detail into some issues glossed over in M&M, as well as to tie together some loose ends. In particular, the interrelationships among some environmental variables mentioned in M&M are discussed here in more detail.

M&M used a form of non-parametric regression that estimated transformations for both the dependent and the independent variables. The algorithm did not produce tables analogous to the ANOVA tables in linear regression. Non-parametric regressions are also used in this paper, but in a form more analogous to standard regression analysis, even allowing "error bars" on the estimated transformations. This should make the resulting models more easily interpreted. Cury and Roy (1989) estimate optimal environmental windows for a number of eastern boundary current regions, including the Peruvian anchoveta. I reestimate these windows for the new data. Finally, Bohle-Carbonell (this vol.) examines fractal dimensions for some of the time series in Pauly and Tsukayama (1987). I estimate a related parameter, fractional differencing, for a larger number of the environmental series, and show how these estimates relate to the models of this paper.

Many of these issues were examined in my original efforts with Jaime Mendo, but were only alluded to in M&M. My knowledge of the Peruvian ecosystem derives from my working with J. Mendo, and while we did not work on this reanalysis together, I would like to acknowledge my debt to him and indicate that this paper would not have been possible otherwise.

Data and Methods

For the population data, I use the estimates of recruitment, parent and female biomass, and egg production in Pauly and Palomares (this vol.) and Pauly and Soriano (this vol.). For the environmental series, I use the corrected alongshore stress given in Bakun and Mendelsohn (this vol.), the turbulence series ("wind speed cubed") in Bakun (1987), the Southern Oscillation Index (SOI) in Brainard and McLain (1987), and the estimates of upwelling and turbulence for Trujillo and Callao in Mendo et al. (1987). For convenience, I will refer to the Bakun estimates of transport and turbulence as the "oceanic" estimates, while the estimates of Mendo et al. (1987) will be referred to by location.

Spectral estimates were calculated for the mean corrected series by first tapering the series using a split-cosine bell taper (Bloomfield 1976)

$$\begin{aligned} .5(1-\cos(\pi(t-.5)/m)), & \quad t=0, \dots, m-1 \\ u_t = 1, & \quad t=m, \dots, n-m-1 \\ .5(1-\cos(\pi(n-t+.5)/m)), & \quad t=n-m, \dots, n-1, \end{aligned} \quad \dots 1)$$

where m is chosen so that $2m/n$ is the desired proportion of the data to be tapered. I have used a 20% taper. Tapering data reduces leakage between frequencies, but tends to make spectral peaks flatter and broader. The discrete Fourier transform of each tapered series was calculated as

$$d_x(\lambda_j) = \frac{1}{T} \sum_{t=0}^{T-1} e^{-i\lambda_j t} x(t) \quad \dots 2)$$

where $\lambda_j = (2\pi j)/T$ is the j th Fourier frequency. The raw (cross)-periodogram is then calculated as

$$P_{xy}(\lambda_j) = d_x(\lambda_j) d_y^*(\lambda_j) \quad \dots 3)$$

where the notation d^* denotes conjugate (transpose). Spectral density matrices were then calculated as the overlapping moving average of the raw periodograms,

$$f_{xy}(\lambda_j) = \sum_{i=-m}^m p_{xy}(\lambda_{j+i}). \quad \dots 4)$$

I have used a value of $m = 5$, giving 22 degrees of freedom.

Most analyses of time series data assume stationarity, or that stationarity can be achieved after applying a relatively short-term filter to the data. This assumption may not be valid for natural processes. Hurst (1951) studied the flows of rivers. Let x_1, x_2, \dots, x_T be the historical sequence of flows. Then the cumulative flows up to time t are

$$S_{ut} = \sum_{j=1}^t x_j, \quad t = 1, 2, \dots, T. \quad \dots 5)$$

Related to reservoir construction is the sequential range

$$R = \max S_{ut} - \min S_{ut} \quad \dots 6)$$

Hurst (1951) looked at the normalized sequential range (or "rescaled adjusted range") where S_{ut} has the mean flow removed and the result is divided by the standard deviation of the flows. If the flows are independent over long time scales, then one would expect that $R/S \sim (T/2)^{1/2}$. However, Hurst (1951) found that for a wide range of river flows $R/S \sim (T/2)^H$ for H in the range (.6,.8). This can be explained in terms of fractional Gaussian noise (fGn) (Mandelbrot and Van Ness 1968, Mandelbrot 1971). Let $B(s)$ be Brownian motion, a stochastic process such that $B(s+u) - B(s)$ are $N(0,1)$ and independent. Then fractional Brownian motion takes the form

$$B_H(t) = \int_{-\infty}^t (t-s)^{H-0.5} dB(s), \quad -\infty < t < \infty \quad \dots 7)$$

or

$$B_H(t) - B_H(0) = \int_{-\infty}^t (t-s)^{H-0.5} dB(s) - \int_{-\infty}^0 (-s)^{H-0.5} dB(s). \quad \dots 8)$$

Discretizing the equation yields

$$b_t(H) = B_H(t) - B_H(t-1). \quad \dots 9)$$

Fractional Gaussian noise can be described by its autocorrelation function

$$C(s) = \frac{1}{2}(|s-1|^{2H} - 2|s|^{2H} + |s+1|^{2H}). \quad \dots 10)$$

Fractional Gaussian noise also exhibits the self-similarity property, that is

$$x(t\lambda) \sim (\lambda)^a x(t). \quad \dots 11)$$

A concept related to fGn is "fractional differencing" (Granger and Joyeux 1980, Hosking 1981) described as

$$(1-B)^d x(t) = e(t) \quad \dots 12)$$

where d is possibly nonintegral, B is the backshift operator, and the $e(t)$ are independently distributed as $N(0, \sigma^2)$. Note that this is not a nonintegral lag operator, but rather an infinitely lagged polynomial in B whose weights die out at a rate given in the autoregressive representation (14). The spectral density of this model is

$$f(\lambda) = \frac{\sigma^2}{2\pi} (2(1-\cos(\lambda))^{-d}, \quad \lambda \neq 0. \quad \dots 13)$$

Granger and Joyeux (1980) derive the following autoregressive representation of a fractionally differenced process

$$\sum a_j x(t-j) = e(t); \quad a_j = \frac{\Gamma(j-d)}{\Gamma(1-d)\Gamma(j+1)} \quad j > 1. \quad \dots 14)$$

Porter-Hudak (1982) and Geweke and Porter-Hudak (1983) show that the power spectrums of the error terms from an fGn process and a fractionally differenced process only differ by a short-term memory component. Thus both models are estimating essentially the same long-term memory component. I find fractional differencing more intuitive, as it is a long-term extension of the usual ideas of differencing and filtering to obtain stationarity. (The first few terms of the expansion of the differencing polynomial are

$$1 - dB - \frac{1}{2}d(1-d)B^2 - \frac{1}{6}d(1-d)(2-d)B^3 \quad \dots 15)$$

The parallels with the usual differencing schemes used to achieve stationarity are immediate.)

Porter-Hudak (1982) and Kashyap and Eom (1988) give methods for estimating the fractional differencing parameter d , based on regressions between the log of the theoretical spectrum and the log of the observed periodogram. The property of concern here is that a process has long-term memory if d is in the range $(0,.5)$; the process has short-term memory if $d < 0$; and the process has infinite variance if $d > .5$ (Granger and Joyeux 1980, Hosking 1981). Both long-term and short-term memory time series models assume that the basic input process is a random variable. The main difference is that in long-memory models any impulse to the system takes a long time to die out. Another way to view this is that the system is sensitive to initial conditions. A small difference in two identical systems at a given time period will be evident for many time periods to come. Depending on the dynamics involved, the difference between the two systems caused by this impulse may grow, rather than disappear through time. The models in M&M as well as the ones in this paper, assume a relationship between anchoveta recruitment and other variables. If this relationship is on the proper scale and is stationary, then long-term memory in any of the predictor variables will not affect the system. However, the length of time ahead that a forecast can be made can be affected by long-term memory, as longer forecast horizons could imply forecasting one of the predictor variables. As errors can propagate in long-memory systems, long-term predictions become unreliable. An alternative is to find another, less direct predictor variable, that is related to anchoveta recruitment at a longer lag. (See also Bohle-Carbonell, this vol., who estimates the fractal dimension of several of the series in Pauly and Tsukayama 1987).

Trends in time-series are estimated using two different algorithms. The first is the "locally-weighted sums of squares" or LOWESS algorithm of Cleveland (1979), and the other is the decomposition algorithm of Kitagawa and Gersch (1984). LOWESS fits to each point a weighted linear regression using some fixed percentage of points surrounding the given point. The regression is then made robust by weighting against outliers. I use a proportion of $F = .05$, which corresponds to two years of data in calculating the smooths in this paper.

Kitagawa and Gersch (1984) assume that an observed time series can be decomposed as

$$y(t) = T(t) + S(t) + A(t) + e(t) \quad \dots 16)$$

where $T(t)$ is a trend component at time t , $S(t)$ is a seasonal component at time t , $A(t)$ is a stationary random component (i.e., and AR component) at time t , and $e(t)$ is an error term. They assume a smoothness prior for the trend and seasonal components, which means that at some level of differencing the component is equivalent to a zero mean normal variate with unknown variance. The degree of differencing and the amount of variance in the random variate causes a tradeoff between the smoothness of the component and the reduction in variance due to that component. This is the same as fitting the discrete equivalent of a smoothing spline for that component (Kohn and Ansley 1988). Kitagawa and Gersch (1984) show that this can be formulated as a state-space model and estimated using a combination of Kalman filtering and maximum likelihood estimation.

The usual regression model has a response random variable Y and p predictor random variables X_1, X_2, \dots, X_p . A set of n independent realizations of these random variables is observed, denoted by $(y_1, x_{11}, \dots, x_{1p}), \dots, (y_n, x_{n1}, \dots, x_{np})$ and it is desired to estimate the conditional expectation $E(Y | X_1, X_2, \dots, X_p)$. Linear regression assumes that the conditional expectation is linear, that is

$$E(Y | X_1, X_2, \dots, X_p) = \beta_0 + \beta_1 X_1 + \dots + \beta_p X_p, \quad \dots 17)$$

and given a sample, estimates of the β_i are usually found by least squares. A natural generalization is to consider additive nonlinear models (Hastie and Tibshirani 1986) of the form

$$E(Y | X_1, X_2, \dots, X_p) = \sum_{j=1}^p s_j(X_j) \quad \dots 18)$$

where the nonlinear functions s_j are to be estimated. This is accomplished by estimating the s_j as an "average" of some part of the data surrounding a point, in this case a scatterplot smoother fit using the backfitting algorithm of Breiman and Friedman (1985). In particular, I use the running lines smoother in Hastie and Tibshirani (1986).

When the functions s_j in generalized additive models are estimated using a fixed span smoother, then it is possible to estimate the degrees of freedom used in forming the estimate of s_j , as well as an analysis of deviance table that is directly analogous to the standard analysis of variance table in regression analysis (Hastie and Tibshirani 1986; see Hastie 1987 for a good description of deviance and how it relates to sums of squares). This allows for a comparison of models using measures such as AIC (Akaike 1977), BIC (Schwarz 1978) or cross-validation. A smaller span produces a closer fit to the observed data (smaller variance), but with a greater bias and larger number of degrees of freedom, equivalent to fitting more parameters in a normal regression model. A larger span is smoother, with smaller bias, but greater variance. The choice of the span is thus a tradeoff between variance and bias, as in most situations where extra parameters can be added to the model. Hastie and Tibshirani (1985) show how to construct 95% confidence intervals for the estimated functions s_j .

Environmental Variables

There are a large number of environmental variables that could be used to model the anchoveta, but brute force searching through all of them can lead to spurious results. The environmental variables available for this study in all likelihood are surrogates for the actual physical processes that affect the anchoveta. It is likely, then, that the dynamics of the variables will be the important element in modeling. While each of these large number of series could be argued to be a surrogate variable, it is possible to separate variables that reflect more direct influences on the fish from those with indirect influences. For this reason, the SOI is not used in any of the direct analyses. The SOI reflects processes distant from the environment of the Peruvian anchoveta. The changes reflected in SOI would have to be reflected in changes in the more local environment to have any effect on the anchoveta. If, however, a local variable is a good predictor of anchoveta recruitment, and there is a strong relationship between the SOI and this local variable, then there exists the possibility for a more extended (longer lead time) forecast.

For completeness, I show the major environmental series with trends estimated using LOWESS. SST (Fig. 1), shows a sharp drop through 1954-1956, and then a peak during the El Niño period of 1957-58. SST remained fairly steady through mid-1971, and then peaked in the 1972 El Niño. The 1983 El Niño produced a strong peak in the series. A slight upward trend in SST is noticeable from 1971 onward.

Oceanic transport (Fig. 2) has been fairly steady, with noticeable increases during the El Niño periods of 1957-58, 1972 and 1983. The 1960s appeared to have been a decade of decreased variance in the transport, and the mean level during the 70s and 80s appears to be somewhat higher.

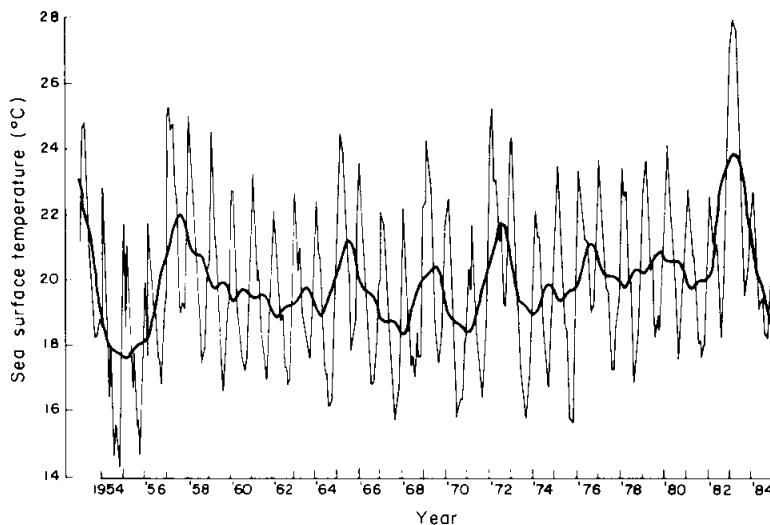

Fig. 1. SST off Peru with estimated local trend line.
Fig. 1. TSM frente a Perú con línea de la tendencia local estimada.

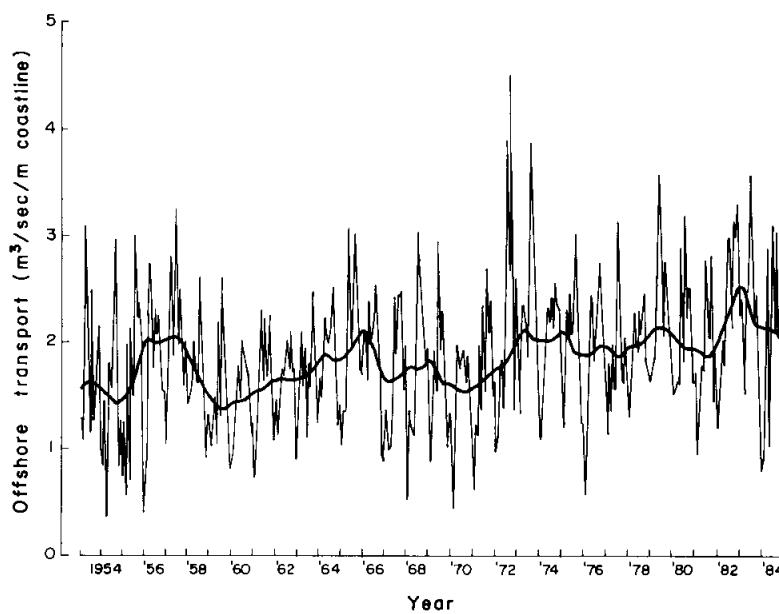

Fig. 2. Oceanic transport off Peru with estimated local trend line.
Fig. 2. Transporte oceánico frente a Perú con línea de la tendencia local estimada.

Transport at Trujillo (Fig. 3) shows the strongest trends among the data series. Transport increased through the El Niño of 1958, and then decreased and stayed relatively constant through the early 1960s. Starting around 1968, transport at Trujillo increased, staying at a higher level through 1972. Transport then dropped sharply till 1974, rose again till 1976, and then declined very sharply until 1982. Coincident with the El Niño of 1983, transport at Trujillo increased to a more normal level. Transport at Callao (Fig. 3) displays similar behavior, except that the drop in 1974 is not as precipitous, and the sharp decline from 1976-1983 is not noticeable.

None of the subsurface series in Brainard and McLain (1987) are used in this paper, even though Bohle-Carbonell (this vol.) suggests that the subsurface has the strongest relationship with the earlier recruitment estimates. I note that, as mentioned in the article, only 20% of the subsurface data are from actual observations; the rest are from an interpolation scheme of unknown statistical properties. It would be difficult to ascertain to what degree any fit using these data was due to the actual physical process or due to the interpolator.

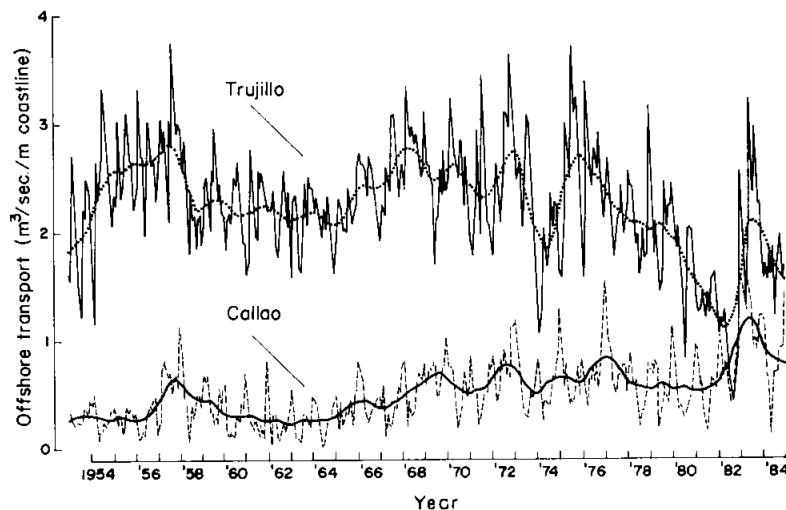

Fig. 3. Transport at Trujillo and Callao, with estimated local trend lines.

Fig. 3. Transporte en Trujillo y Callao, con líneas de las tendencias locales estimadas.

SST also is not used as a predictor. There are good *a priori* reasons for believing that SST would influence anchoveta recruitment. Unfortunately, several of the estimates of anchoveta consumption by other species (Muck and Pauly 1987; Pauly et al. 1987; Muck and Sanchez 1987) make explicit use of SST to modify the amount consumed. In the model of Muck and Sanchez (1987) for mackerel and horse mackerel, the offshore biomass of these fish are assumed at equilibrium sizes, but the relative number of mackerel close to shore varies with SST. Estimated consumption by these species are thus proxy variables for SST. Using SST in any further analysis leads to an obvious, direct bias. SST is also correlated with many of the other environmental variables, which may lead to indirect biases which cannot be totally avoided.

If the environmental variables are viewed as surrogates for a physical process in the ocean, one method for selecting which environmental variables to use in modeling is to see what unique information (in the statistical sense) each of the series contains. If each of the series contains essentially the same information, then there is little matter which is used. If the variables differ greatly in the information contained, then variables should be selected *a priori* based on knowledge of the fish and of the oceanographic processes likely to affect them.

Bakun and Parrish (1982) and Parrish et al. (1984) give cogent arguments as to why wind-induced transport should be an important factor in recruitment. Lasker (1978) has argued that turbulence affects early survival of larvae by affecting the concentration of available food. Based on these arguments, the transport and turbulence indexes discussed above are natural starting points for the analysis. The SOI will also be examined in relationship to these variables to see if it is reflected in any of these series.

Bakun's estimate of transport and wind is based on averaging a broad area off the coast of Peru, and is dominated by offshore observations. The series of Mendo et al. (1987) are from airports by the coast in Trujillo and Callao, and these authors present anecdotal evidence that these series accurately reflect the nearshore surface winds over the water. If these series differ in their information, then a basis for choosing a series is which area (nearshore or offshore, north or south) most likely influences the areas where the anchoveta are spawning.

The oceanic transport has the expected red noise spectrum at low frequencies, with a strong peak at a yearly frequency and small peaks at the harmonics of the yearly frequency (Fig. 4). Transport at Trujillo and Callao have a weak seasonal signal, and are dominated by the red noise spectrum (Fig. 4). The coherences between the oceanic transport and the transport at Trujillo and Callao are relatively low except at a few frequencies (Fig. 4) and the series are significantly out of phase. This implies that the inshore measures of wind and the oceanic measures contain quite different information about the environment.

Similarly, transport at Trujillo has significantly different dynamics than transport at Callao (Fig. 5). The spectrum of Trujillo transport has a more dominant red noise component, while the

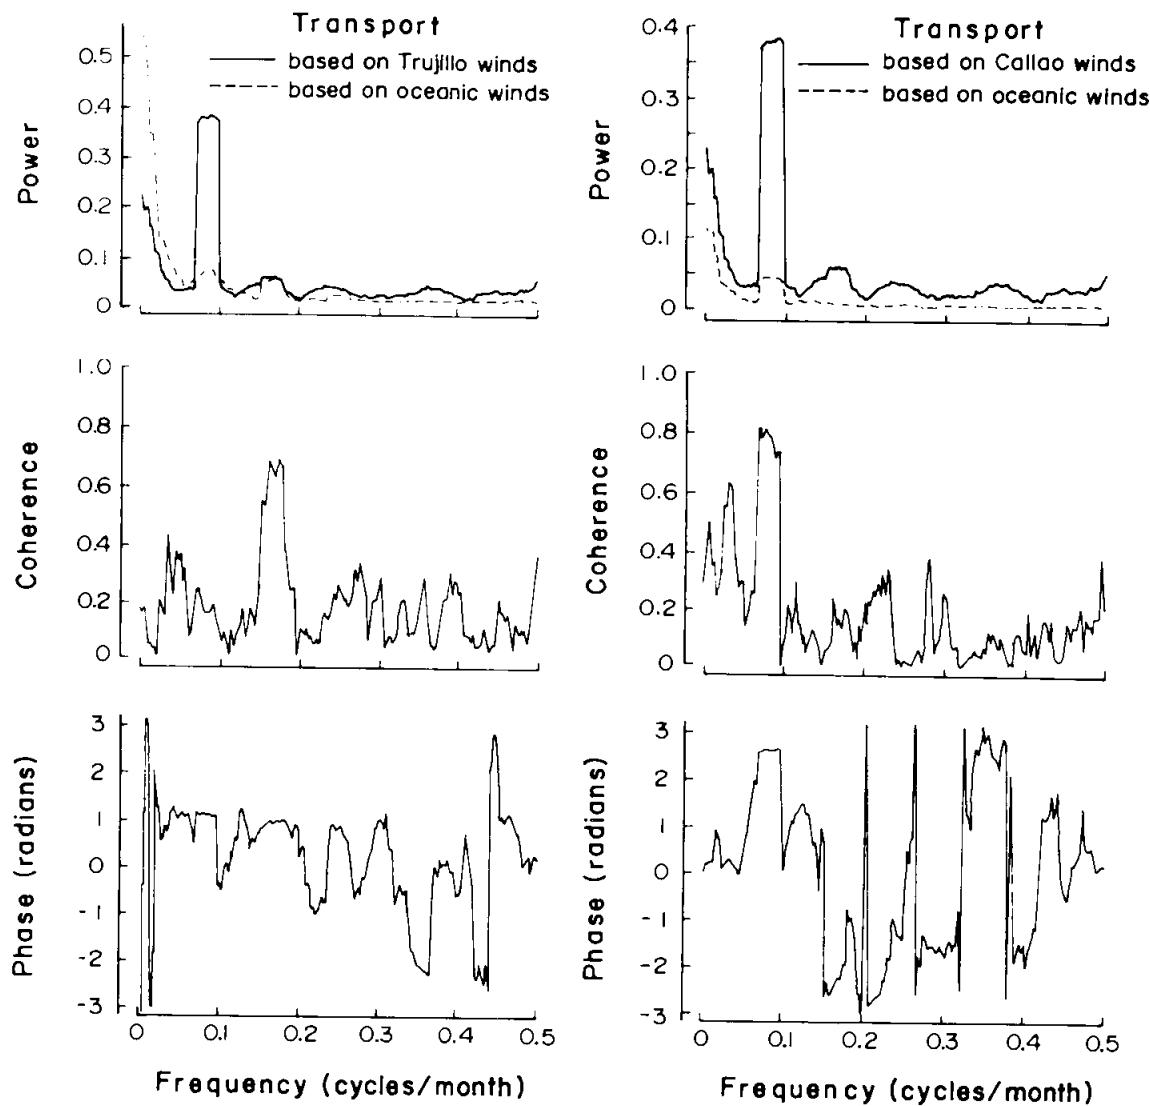

Fig. 4. Spectral analysis of transport off Peru (oceanic winds), Trujillo and Callao (local winds) transport.
Fig. 4. Análisis espectral del transporte frente a Perú (vientos oceánicos), transporte de Trujillo y Callao (vientos locales).

Callao transport has a relatively stronger seasonal cycle. The coherences are not particularly large, and the two series are significantly out of phase. A similar result is valid for the turbulence index at Trujillo and Callao (not shown). Thus, none of the three transport series closely reflects what is occurring in the other two series.

The SOI and oceanic transport have similar spectra, particularly at the yearly frequency and at a peak that would correspond roughly to the occurrence of El Niño (Fig. 5). The two series are highly coherent at these frequencies, and almost 180° out of phase. The same is not true of the SOI and Trujillo transport (Fig. 6), where the main coherence is at the half-yearly frequency. The SOI appears to be a significant advance indicator of what will happen offshore at the longer frequencies, but not of the more inshore behavior.

Long-term memory, if it exists in the ocean, has implications for forecasting too far ahead any process that depends on variables that exhibit this property. The more oceanic series, such as SOI and transport and turbulence calculated over the broad area, exhibit a similar, weak degree of long-term memory (Table 1). The more inshore measures exhibit a stronger long-term memory, approaching infinite variance. As I will be arguing that the more inshore environmental series are the most appropriate, the models involved will be using variables of limited predictability.

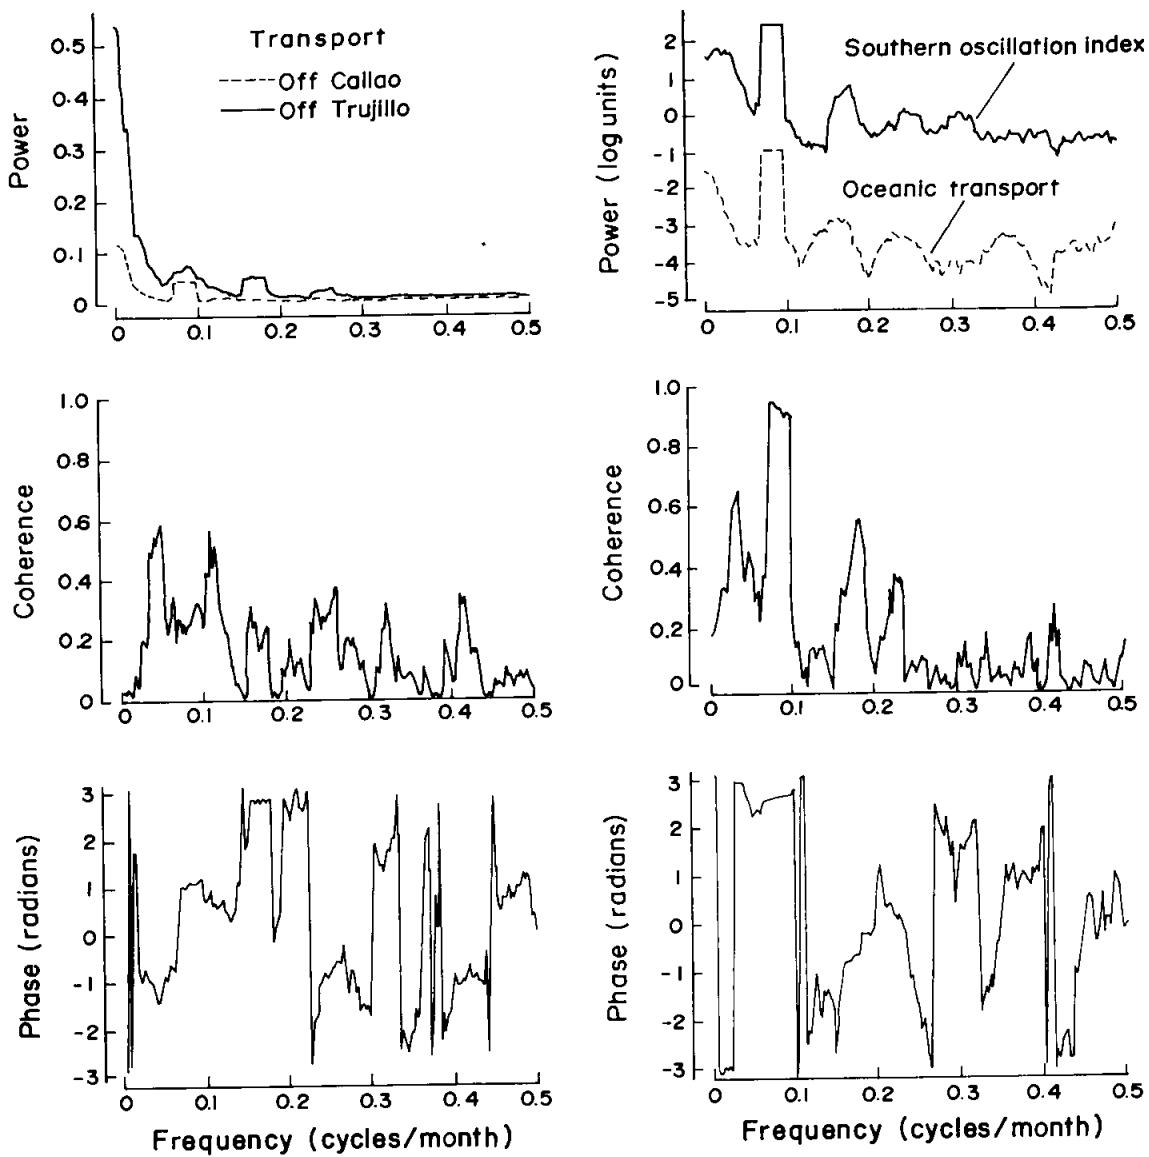

Fig. 5. Spectral analysis of local transport at Trujillo and Callao, of transport off Peru and of SOI.

Fig. 5. Análisis espectral del transporte local en Trujillo y Callao, del transporte frente a Perú y del Índice de Oscilación Sur (SOI).

Turbulence and transport, though both wind-induced, measure very different processes in terms of the anchoveta. If the wind does affect anchoveta recruitment, resolving if it is mainly through transport (most likely transporting larvae offshore) or mainly through turbulence (by affecting food availability to larvae) is an important issue. At Trujillo, transport and turbulence are highly coherent except at very high frequencies, and in phase at all frequencies (Fig. 6). As mentioned in M&M, the wind at Trujillo is predominantly from one direction, so that transport is close to wind speed squared, while turbulence is wind speed cubed. The difference in behavior at higher frequencies appears to be one of scale, where turbulence is more variable since it is the cube of the observed speed. As I will be using mostly non-linear techniques to model the data, this difference becomes negligible. (For example, on a log scale, the two series will differ by a multiplicative constant, which can be factored into the parameter on the series. This would not be the case if the wind varied greatly in its direction, so that the alongshore stress differed greatly from the wind speed squared). A similar result was found for Callao. Thus, though biologically there are significant differences between transport and turbulence, statistically for the inshore wind series, it will not be possible to discriminate if an effect is due to transport or turbulence.

Biological Series

One of the obvious but major problems in studying fisheries is that it is rarely possible to obtain a reliable direct census of the fish population. Instead, "sampling" is used to obtain estimates. Usually the sampling scheme is of no statistical design, but instead depends on uncontrollable factors such as fishermen's behavior. The actual data, or the observables, are things like catch and effort statistics, length distributions, etc. While a variety of schemes have been devised to use this information to estimate characteristics of the population, the inescapable fact is that only the catch, effort, length distribution measurements, etc. are data, while the rest are estimates.

A property of calculating estimates from data is that degrees of freedom are used. In most cohort-analysis schemes, many degrees of freedom are used in calculating population and recruitment estimates. As the schemes are operating on autocorrelated data, they also act as filters on the observed data, changing the importance of different frequencies. When the same algorithm is used to jointly estimate many series, it is likely that just due to the estimation scheme, there will be a certain amount of cross-correlation in the resultant estimates.

It has been common to treat estimates of recruitments and of parents as data with the usual degrees of freedom. (Ultimately I will be forced to do the same (it is all there is to work with), but not without some careful checks on artificially-induced correlation.) In effect, when I use the recruitment estimates to estimate a relationship with another variable, I am fitting a composite function $f(g(x))$ of the original catch, effort and length data, where x is the original data, $g()$ is the operation performed by the cohort analysis, and $f()$ is the final relationship. If two intermediate estimates of this composite process exhibit a strong relationship, it cannot be said for certain that this relationship is real, or is just a product of the estimation scheme. Thus if parents and recruits are strongly related, it may be an artifice of cohort analysis. This will make it difficult to interpret many of the results to follow.

As mentioned previously, in attempting to correct for mortality other than from fishing, the resulting consumption estimates are functions of SST, and this feeds into the recruitment and parent estimates. Thus SST, and any variable highly correlated with SST, will have an unknown degree of spurious correlation with the population estimates. Most of the transport series display a reasonable degree of correlation with SST.

The new estimates of recruitment are shown on Fig. 7, along with the old ones. The new estimates exhibit less relative variation than do the original estimates, as was anticipated by Pauly (1987) who wrote that "it can be hypothesized that the [new] recruitment and biomass [...] will be somewhat smoother". Both series show an increase from 1957 to 1958, during El Niño, but in the original estimates this increase produced a change in mean level in both parent biomass and in recruitment, while in the new estimates the recruitment level drops right after the end of the El Niño. The new estimates start increasing from about 1963 to 1969-1970, after which both the new and old estimates show a similar decrease. The old estimates then show a more significant relative increase than do the new estimates. The parent biomass follows a similar pattern (Fig. 8).

The estimated AR component of the new recruitment estimates (Fig. 9) is relatively less variable than the AR component of the old estimates, particularly during the 1960s. The log of the ratio of recruits to parent biomass three months earlier (Fig. 10) is relatively constant except for the El Niño years of 1972 and 1982-1983. The ratio with the number of eggs shows a similar pattern (not shown), though the decrease during the 1972 El Niño is not as sharp. The spectrum of both the recruit series and the log of the recruits (Fig. 11), is dominated by a red noise component with a weak yearly signal.

The picture presented by these graphs is of a highly persistent, stable series where the only significant change occurred during a one or two year period around 1969. In fact, the trend in the new recruitment estimates mirrors closely what would be expected from the smoothed (5-year averaged) trends in catch and effort in Agüero (1987). After all the corrections, except for questions of scale, the recruitment estimates tend to mirror catch-per-unit-effort (C/f).

Some of the smoothness in the new recruitment estimates are due to mackerel consumption being a surrogate for SST (Pauly 1987). During El Niño years, for example, the catch rate tended to decrease. In the previous models, this results in variability in the recruitment estimate. In the

new series, the mackerel are assumed to come closer to shore as SST warms, increasing mackerel consumption and thereby increasing the estimated population sizes. Mackerel consumption has prewhitened the inputs into the estimation algorithm based on the variation in SST. This does not necessarily mean that prewhitening the inputs is incorrect, but it does explain why there are such differences in the two sets of recruitment estimates.

Comparing the parent series (Fig. 8) with the ratio of recruits to parent biomass (Fig. 10), it is clear that the trend in the log of the ratio is largely explained by changes in the parent biomass, particularly if a mild density dependence is assumed. In the next section I will return to this point more formally, but it brings me back to the initial discussion of this section. If the estimated parent biomass and the estimated recruitment appear to be closely related, is it truly a feature of the population dynamics or a feature of the method that jointly estimates both series?

Data Analysis

In M&M it was found that the monthly recruitment estimates were so highly autocorrelated that it was necessary to examine the monthly series, mildly smoothed (two month nonoverlapping averages), across years. This allowed estimation of the interyear variability as well as to obtain some idea of the intrayear variability. The new recruitment estimates have an autocorrelation of .99 at a lag of 1 month. Even after first differencing, the series is still nonstationary, with the autocorrelations positive and significant at a lag of well over 20 months. This behavior in the autocorrelation function is expected, given the estimated spectrum of the series. Nonoverlapping averages can be formed to try to find a scale at which the series decorrelates and has a more stationary autocorrelation function. However, it is necessary to average almost on a yearly basis to achieve a reasonable degree of stationarity, at which point there is no reason to use anything except the yearly averages.

Following M&M, I have formed 2-month averages of recruitment and parent biomass, as December-January, February-March, etc. The value for December 1952-January 1953 is just the January value, as average, not total values, are used. Each of these series will be examined across

years. Senocak et al. (this vol.), based on the egg survey data in Santander (1987), show that the bulk of the egg distribution throughout the year is inshore rather than offshore. From 1961-1972, for most months the center of the egg distribution is more northerly, around Trujillo rather than Callao. From 1972 onward, the center shifts, being at many times evenly distributed along the coast from Trujillo to Callao, or in some months, clearly centered at Callao. Given the differences in the dynamics of the wind data series analyzed above, this argues for using either the Trujillo or Callao series. As Trujillo is more of a center of the egg distribution in these charts than is Callao, transport at Trujillo, as in M&M, will be used as the environmental variable. As mentioned previously, when a nonlinear analysis is used, this cannot readily be resolved from turbulence at the same location.

Additive models were estimated for the log of recruitment as the response variable, with parent biomass 2 averaged time periods prior (June-July parent biomass predicts October-November recruitment etc.) and Trujillo transport in the previous September and November as the predictor variables. The results in M&M, in Cury and Roy (1989), and the graphical results above all suggest that recruitment should be modeled on a log scale. The span for the transformations of the parent biomass were chosen using cross-validation, which explicitly calculates a tradeoff between the degrees of freedom and the variance of the fit. The estimated transformations of parent biomass (Fig. 12) are approximately that of a log transformation in each case. Thus on a log-log scale, for the period April through November, over 90% of the variance of the recruitment is explained by the parent biomass at the time of birth (Table 2).

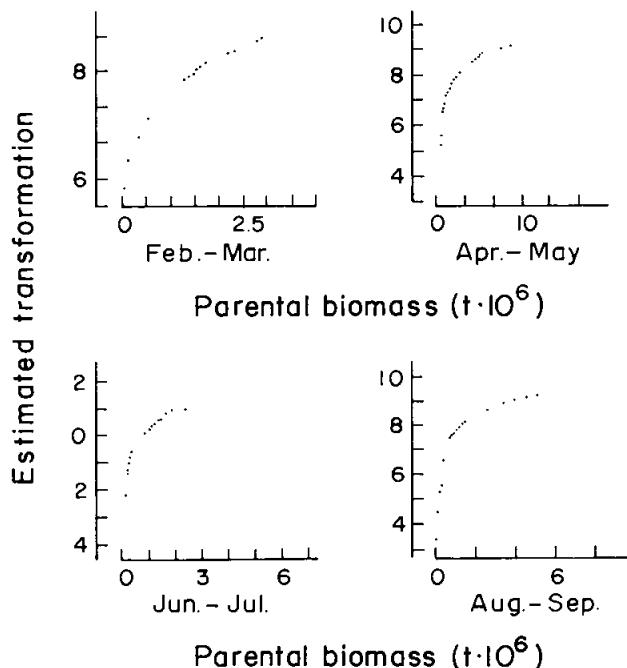

Fig. 12. Estimated transformations of the parent biomass when predicting anchoveta recruitment in a generalized additive model. All four transformations are close to a log transformation.
Fig. 12. Transformaciones estimadas de la biomasa parental cuando se pronostica el reclutamiento de anchoveta en un modelo aditivo generalizado. Las cuatro transformaciones son próximas a la transformación logarítmica.

For the period from December through March, the estimated r^2 is around .60 (Table 3). The period from December through March is the period of lowest recruitment (Fig. 13A). Therefore the additive models work best during the most important periods of recruitment. On a log scale (Fig. 13B), the monthly recruitment values underline what I have said previously. Recruitment was fairly constant until 1969, with a big peak in 1969, followed by a drop to a new equilibrium

It is entirely possible that recruitment is tightly coupled to parent biomass as these models suggest. That then leaves open the question of why there was such a large parent biomass in 1969. Certainly the recruitment feeding into that year was nothing special compared to previous years; and graphs of the possible environmental factors by month (not shown), do not reveal anything unusual at this time period. The other possibility, of course, is that this is a feature of jointly estimating parents and recruits on such a fine time scale. The added degrees of freedom seemingly brought about from monthly recruitment estimates, at least for the purposes of this

paper, do not seem to be there. It appears that all the adjustments in the estimates, while perhaps revealing interesting features in the dynamics of anchoveta recruitment, have also limited the amount of independence in the data.

Cury and Roy (1989) estimate transformations for the yearly averages for the old estimates using the ACE algorithm of Breiman and Friedman (1985). For completeness, I have redone this for the new recruitment estimates (Fig. 14A). Cury and Roy's basic conclusions remain unchanged. The ACE algorithm does not provide an analysis of variance, and given the correlation between transport and turbulence at Trujillo, starting with the variable of lower dimension appears wise. For this reason I refit this model using generalized additive models.

The analysis of deviance for a span of .20 (Table 4) shows that the single best predictor is transport, which for this choice of span explains 60% of the variance. With so few data points, the fit does vary with the choice of span, from roughly 50% to 60%. In all cases, however, the fit due to transport was much higher than that due to parent biomass. When both variables are included, the r^2 increases to .78, which suggests that there is also strong intercorrelation between the parent biomass estimate and turbulence. The range of r^2 for different values of the span was .68 to .78.

The estimated transformations (Figs. 14B and 14C) for both variables resemble a log transformation, and the 95% confidence intervals (Hastie and Tibshirani 1985) are reasonably tight around the mean and preserve the same shape. While the choice of span affects the estimated degrees of freedom, the shape of the transformation is unaffected by the choice of span.

The effect of the transformations can also be viewed by fitting a smoothed surface to the 3-dimensional data (Fig. 15). (This is also a phase plot of recruitment for both datasets). The transformed surface is unimodal and smoother. It is clear that the relationships on the raw scale are nonlinear, while those on the transformed scale are linear in each dimension. While the model is only an additive approximation, it has caught the essence of what information is contained in the data.

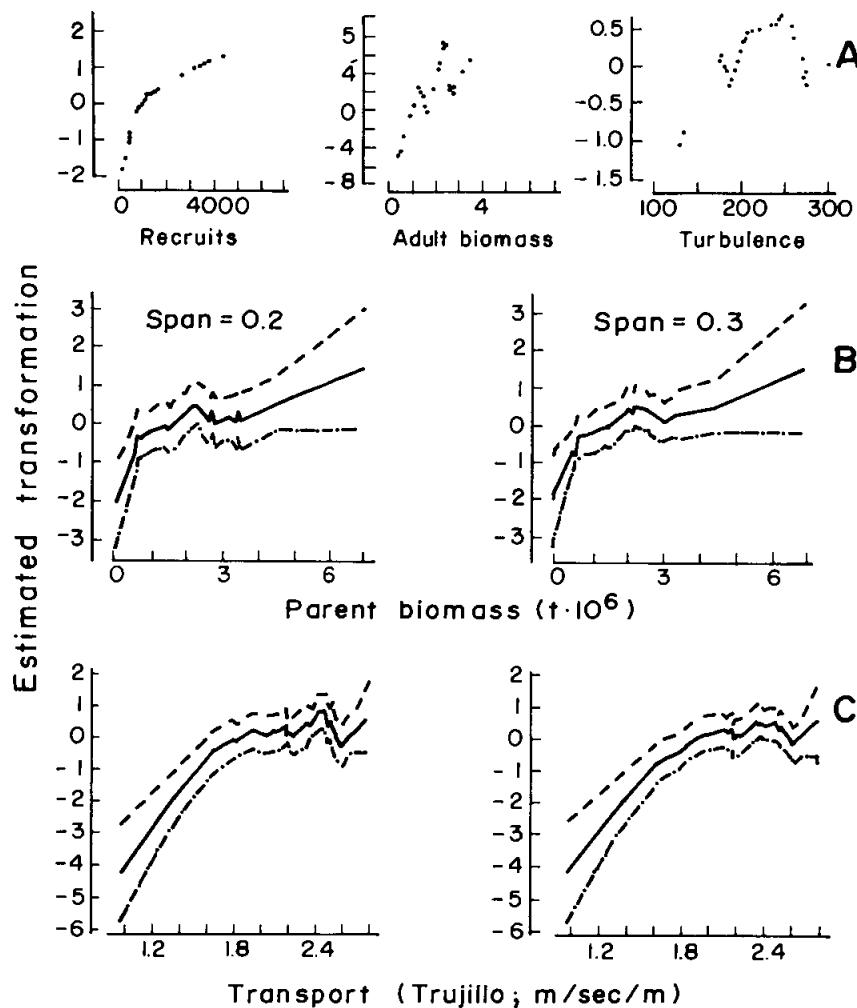

Fig. 14. Estimated transformations (A) from the ACE algorithm, redoing the analysis of Cury and Roy (1989) for the new recruitment estimates. (B) Parent biomass in a generalized additive model for predicting yearly anchoveta recruitment. Dashed lines are 95% confidence intervals for the transformations. Discussion

I have shown that the new estimates of recruitment are much smoother than the previous estimates, with different trends, except for the sharp decrease following 1969 evident in both sets of estimates. Part of the difference between the two sets of recruitment estimates appears to be due to the fact that several estimates of anchoveta consumption, particularly that for mackerel, are surrogates for SST and tend to cause the recruitment estimates to be filtered (smoothed) based on the variation in the SST series.

The new recruitment estimates, even more so than the previous estimates, are highly autocorrelated, even after differencing. Essentially all of the variance in the monthly recruitment series can be modeled by a simple AR(1) model. It is questionable that this represents the true dynamics of recruitment, and certainly would follow, rather than predict, any sudden changes in the population dynamics. Nonoverlapping time averaging requires forming yearly averages to achieve a satisfactory level of stationarity.

Bimonthly averages of recruitment, viewed across years, are extremely correlated with the log of parent biomass when the recruits were born. The high degree of fit is suspicious, and may be due to the fact that both series were jointly estimated. This left little choice but to analyze yearly averages.

A generalized additive model was then estimated for the yearly averages, using the average parent biomass over the year, and the average transport at Trujillo. The resulting estimates suggest that on a nonlinear scale, about 75% of the variance in the recruitment estimates can be explained by these two series. The analysis suggests that large parent biomass, and a reasonable level of transport produce the best recruitment. Evidence is presented that these nonlinear estimates are relatively stable.

Parrish et al. (1984) argue that transport should be an important variable in the Peruvian system, but due to the dominance of wind in a single direction, it is not possible to resolve whether it is transport, turbulence or some combination of the two (as argued by Cury and Roy 1989) affecting the fish. Even at the yearly scale it is not possible to say what part of the relationship between the parent biomass and the recruitment estimates are due to correlation from their joint estimation. This is compounded by the fact that transport is correlated with SST, and all the population estimates have been influenced by changes in SST.

Unlike in M&M, the present model, if valid, has much explanatory power but little predictive use since all terms are contemporaneous and are averaged over a year. It may well be possible to construct models that will forecast using lagged terms to approximate the proper model, but it would be premature to do so at this time. More important at the moment is to study the various methods of cohort analysis to obtain either theoretical or empirical estimates of the expected cross-correlation functions between recruits and parents due to the fact that they are being jointly estimated in a model that uses up most of the degrees of freedom in the data. (Simulations based on model-generated data with recruitment a random variable, possibly autocorrelated, could give estimates of the expected level of correlation when none is present.) Further, some estimates of the likely base level of correlation with any environmental variable correlated with SST should also be ascertained.

With these results, more valid estimates of significance of a model would be possible. The yearly model in this paper, on the surface, has an intuitive biological interpretation, but this does not guarantee its validity. If all the new population estimates are valid, the existing interpretations of what has occurred in the anchoveta fishery would have to be greatly modified. The new estimates suggest a population that essentially stays in equilibrium until some single event changes the mean level. A new mean level is then found, until another shock comes to the system. The most likely cause of these shocks are environmental changes, but as examined here and in Bohle-Carbonell (this vol.), the environment around Peru exhibits long-term memory, so that monitoring of the environment would have to become an important part of the predictive process.

This implies that once local mechanistic models can be validated, then the use of surrogate variables, such as SOI, that may "monitor" the ocean further ahead, could be useful in forming a predictive model. I have not examined this possibility in detail, but I have presented evidence based on the interrelationship between the SOI and oceanic transport, that this longer lead prediction is at least physically plausible.

Acknowledgements

I thank Dr. Daniel Pauly for inviting this contribution, and Mr. Jaime Mendo for discussions and insights into the Peruvian anchoveta fishery. My colleagues at PFEG have provided helpful comments on earlier drafts. The GAIM program used to estimate the generalized additive models was provided by Drs. Trevor Hastie and Robert Tibshirani. Rob Tibshirani has generously answered questions about the program.

MUCK, P. 1989. Major trends in the pelagic ecosystem off Peru and their implications for management, p. 386-403. In D. Pauly, P. Muck, J. Mendo and I. Tsukayama (eds.) The Peruvian upwelling ecosystem: dynamics and interactions. ICLARM Conference Proceedings 18, 438 p. Instituto del Mar del Perú (IMARPE), Callao, Perú; Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ) GmbH, Eschborn, Federal Republic of Germany; and International Center for Living Aquatic Resources Management (ICLARM), Manila, Philippines.

Abstract

This paper summarizes the observations on changes in biomass, individual growth, species dominance, feeding strategy and oceanographic parameters reported from the Peruvian upwelling ecosystem from 1953 to 1987. It is concluded that overfishing of the Peruvian anchoveta (*Engraulis ringens*) is the key factor behind the observed biomass changes in all important species in the system. The hypothesis is presented that stronger exploitation of horse mackerel (*Trachurus murphyi*), a major anchoveta predator, could help alleviate the present disequilibrium between predators and prey fishes, and lead to higher sustained multispecies yield.

Resumen

Esta contribución sumariza las observaciones sobre cambios en biomasa, crecimiento individual, dominancia de especies, estrategia de alimentación y parámetros oceanográficos del ecosistema de afloramiento peruano reportados de 1953 a 1987. Se concluye que la sobrepesca de la anchoveta peruana (*Engraulis ringens*) es el factor determinante en los cambios de biomasa observados en todas las especies importantes del sistema. Se presenta la hipótesis de que una más fuerte explotación del jurel (*Trachurus murphyi*), un gran predador de la anchoveta, ayudaría a aliviar el desequilibrio actual entre los peces predadores y presa, y conducir a un mayor rendimiento sostenido multispecífico.

Introduction

This contribution presents a review of the major trends of biotic and abiotic factors in the Peruvian upwelling ecosystem, for the years 1953 to 1987, based on the time series data in Pauly and Tsukayama (1987) and ancillary data recently collected by IMARPE and PROCOPA staff.

The aim of this contribution is to enable fishery scientists and managers to obtain an understanding of the complexity of, and of the interactions within the Peruvian upwelling ecosystem. Such understanding is necessary for economic management of the Peruvian pelagic fisheries, which are linked to the marine ecosystem through various feedback loops.

*PROCOPA Contribution No. 90.

Materials and Methods

The following atmospheric and oceanographic parameters are available as monthly time series, for the period 1953 to 1982 or later:

- Solar radiation (Bakun 1987)
- Atmospheric pressure (Bakun 1987)
- Southern Oscillation Index (Brainard and McLain 1987)
- Total cloud amount (Bakun 1987)
- Wind stress on sea surface (Bakun 1987)
- Offshore Ekman transport (i.e., upwelling) (Mendo et al. 1987; Bakun and Mendelsohn, this vol.)
- Offshore Ekman velocity (Bakun 1987)
- Turbulence (Bakun 1987; Mendo et al. 1987)
- Sea surface temperature (Pauly and Tsukayama 1987b; Bakun 1987; Tsukayama, this vol.)
- Depth of SST -2°C (Brainard and McLain 1987)
- Depth of SST -14°C, i.e. thermocline (Brainard and McLain 1987)
- Radiative heat loss (Bakun 1987)
- Evaporative heat loss (Bakun 1987)
- Net heat exchange (Bakun 1987)
- Heat content to depth of SST -2°C (Brainard and McLain 1987)
- Potential new primary production (Chavez et al., this vol.; Mendo et al., this vol.).

Table 1 summarizes the time series data of biomass used here for inferences concerning the major species of fish, mammals and birds inhabiting the Peruvian upwelling ecosystem. Table 2 summarizes some fishery statistics, to be discussed further below as well as some of the abovementioned oceanographic time series, all put on an annual basis.

These data refer to the area off Peru ranging from 4°-14°S, and about 75 km offshore. This area of approximately 100,000 km² shall be called here the Main Anchoveta (distribution) Area, or MAR.

The "match" between time series was quantified using two approaches. The first of these was to convert the time series in Tables 1 and 2 into series of signs, depending on whether interannual changes reflected an increase (+) or a decrease (-). Testing was based on the assumption that when there is no significant match between two time series, the occurrence of each of the four possible combinations of signs (- -; + +; + - and - +) should be equal. Or more generally: the sum of pairs with different signs (- + or + -) should be equal to the sum of pairs with the same sign (- - or + +); this can be tested using a chi-square test.

The other approach, also based on counting signs, involved the definition of a degree of coincidence (DC), computed from

$$DC = | 50 - Obs | \quad ...1)$$

where 50 refers to the expected percentage of - - or + + pairs for interyear changes, and Obs refers to the observed percentage of such pairs. DC thus has a value of 50 when all (i.e., 100%) of the paired signs are of the type + -, - + or + +, - -, and a value of zero when the paired signs are equal in numbers. DC values have been estimated for lags of 0 and 1 year.

Results and Discussion

Means and Coefficients of Variation

Table 1 and Fig. 1 show that the MAR was (and in fact still is) dominated by anchoveta, followed by sardine and horse mackerel, each of them representing about 25% of the biomass of anchoveta. Hake and mackerel, finally contribute(d) about 10% of the biomass of anchoveta.

The biomass of bonito, guano birds (three species) and pinnipeds (two species) are, in this context, negligibly small: each of them contributed less than 1% of the biomass of anchoveta.

Table 1. Annual time series of the biomasses of major elements of the Peruvian upwelling ecosystem (adjusted to 4-14°S), as used to discuss trends.

A = anchoveta *Engraulis ringens*; 1953 to 1980: based on VPA (from Pauly et al. 1987a); 1980-1983 interpolated; 1984-1987 based on echoacoustics (from Vilchez et al. 1988); 1988 based on echoacoustics (IMARPE, unpublished); in t*10⁶.

B = sardine *Sardinops sagax*; 1953 to 1982 based on egg surveys (from Muck et al. 1987); 1983-1987 based on echoacoustics (from Vilchez et al. 1988); 1988 based on echoacoustics (IMARPE, unpublished); in t*10⁶.

C = bonito *Sarda chiliensis*; 1953-1982 based on catch and ancillary data on "large" bonito (from Pauly et al. 1987b); 1983-1987: based on IMARPE catch data; in t*10⁶.

D = nearshore (≤ 75 km) population of mackerel *Scomber japonicus*; based on larval survey, acoustics and population model (from Muck et al. 1987 and Muck and Sanchez 1987); in t*10⁶.

E = nearshore (≤ 75 km) population of horse mackerel *Trachurus murphyi*; based on larval survey, acoustics and population model (from Muck et al. 1987 and Muck and Sanchez 1987); in t*10⁶.

F = hake *Merluccius gayi*; based on VPA (from Espino and Wosnitza-Mendo, this vol.); in t*10⁶.

G = sea lion *Otaria byronia* based on beach counts and population model (1953-1984 from Muck and Fuentes 1987; 1985-1987 assumed equal to 1982 level; P. Majluf, pers. comm.); in t*10³.

H = fur seal *Arctocephalus australis*; based on beach counts and population model (1953-1984 from Muck and Fuentes 1987; 1985-1987 assumed equal to 1982 level; P. Majluf, pers. comm.); in t*10³.

I = cormorant *Phalacrocorax bougainvillii*; monthly counts (1953-1982 Tovar et al. 1987) converted to biomass using relationships in Muck and Pauly 1987; 1984-1987 courtesy of H. Tovar; in t*10³.

J = booby *Sula variegata*; monthly counts (1953-1982 Tovar et al. 1987) converted to biomass using relationships in Muck and Pauly 1987; 1984-1987 courtesy of H. Tovar; in t*10³.

K = pelican *Pelecanus thagus*; monthly counts (Tovar et al. 1987) converted to biomass using relationships in Muck and Pauly 1987; 1984-1987 courtesy of H. Tovar; in t*10³.

L = All teleosts (A to F); in t*10⁶.

M = All species (A to K); in t*10⁶.

Tables 1 and 2 also include information on the relative variability of each time series as expressed by its % coefficient of variation (C.V. = s.d. * 100/ \bar{X}). As might be seen, the lowest observed C.V. values were those of the oceanographic parameters, with temperature (C.V. = 6%) being the least, and upwelling (C.V. = 40%) being the most variable time series. The variation of biomass in Table 1 tends to be higher: mackerels (C.V. = 20.3%) varied least while the cormorants (C.V. = 105%) varied most.

Table 2. Selected time series on the Peruvian pelagic fisheries and the upwelling ecosystem.

Tabla 2. Series de tiempo seleccionadas sobre la pesquería pelágica peruana y el ecosistema de aforamiento.

A = number of purse seiners (from Agüero 1987).

B = fleet capacity (tonnes/vessel) (1953-1969: adjusted from Jordan 1982; 1970-1980: from Agüero 1987; 1981-1987: M. Agüero, pers. comm.).

C = total catch of pelagic fishes (= anchoveta + sardine + bonito + mackerel + horse mackerel, in t * 10³) (IMARPE, unpublished data).

D = nominal catch of anchoveta (1953-1983: from Agüero 1987; 1984-1987: IMARPE, unpublished data).

E = exploitation rate of anchoveta (= annual catch/biomass; biomasses from Pauly et al. 1987a).

F = sea surface temperature in °C, Peruvian coast from 4-14°S; 1953-1982 from Pauly and Tsukayama (1987); 1983-1987 from IMARPE (unpublished data).

G = Ekman transport (i.e., upwelling) near Trujillo, in m³/sec/100m coastline; from Mendo et al. (1987).

H = Ekman transport (i.e., upwelling) near Callao, in m³/sec/100m coastline; from Mendo et al. (1987).

I = Turbulence index (i.e., "wind cubed") near Trujillo, in m³/sec³; from Mendo et al. (1987).

J = Turbulence index (i.e., "wind cubed") near Callao, in m³/sec³; from Mendo et al. 1987.

K = potential new production off Peru, in gC/m²/day, as estimated by Chavez et al. (this vol.).

L = potential new production near Trujillo, in gC/m²/day, as given in Table 3 of Mendo et al. (this vol.).

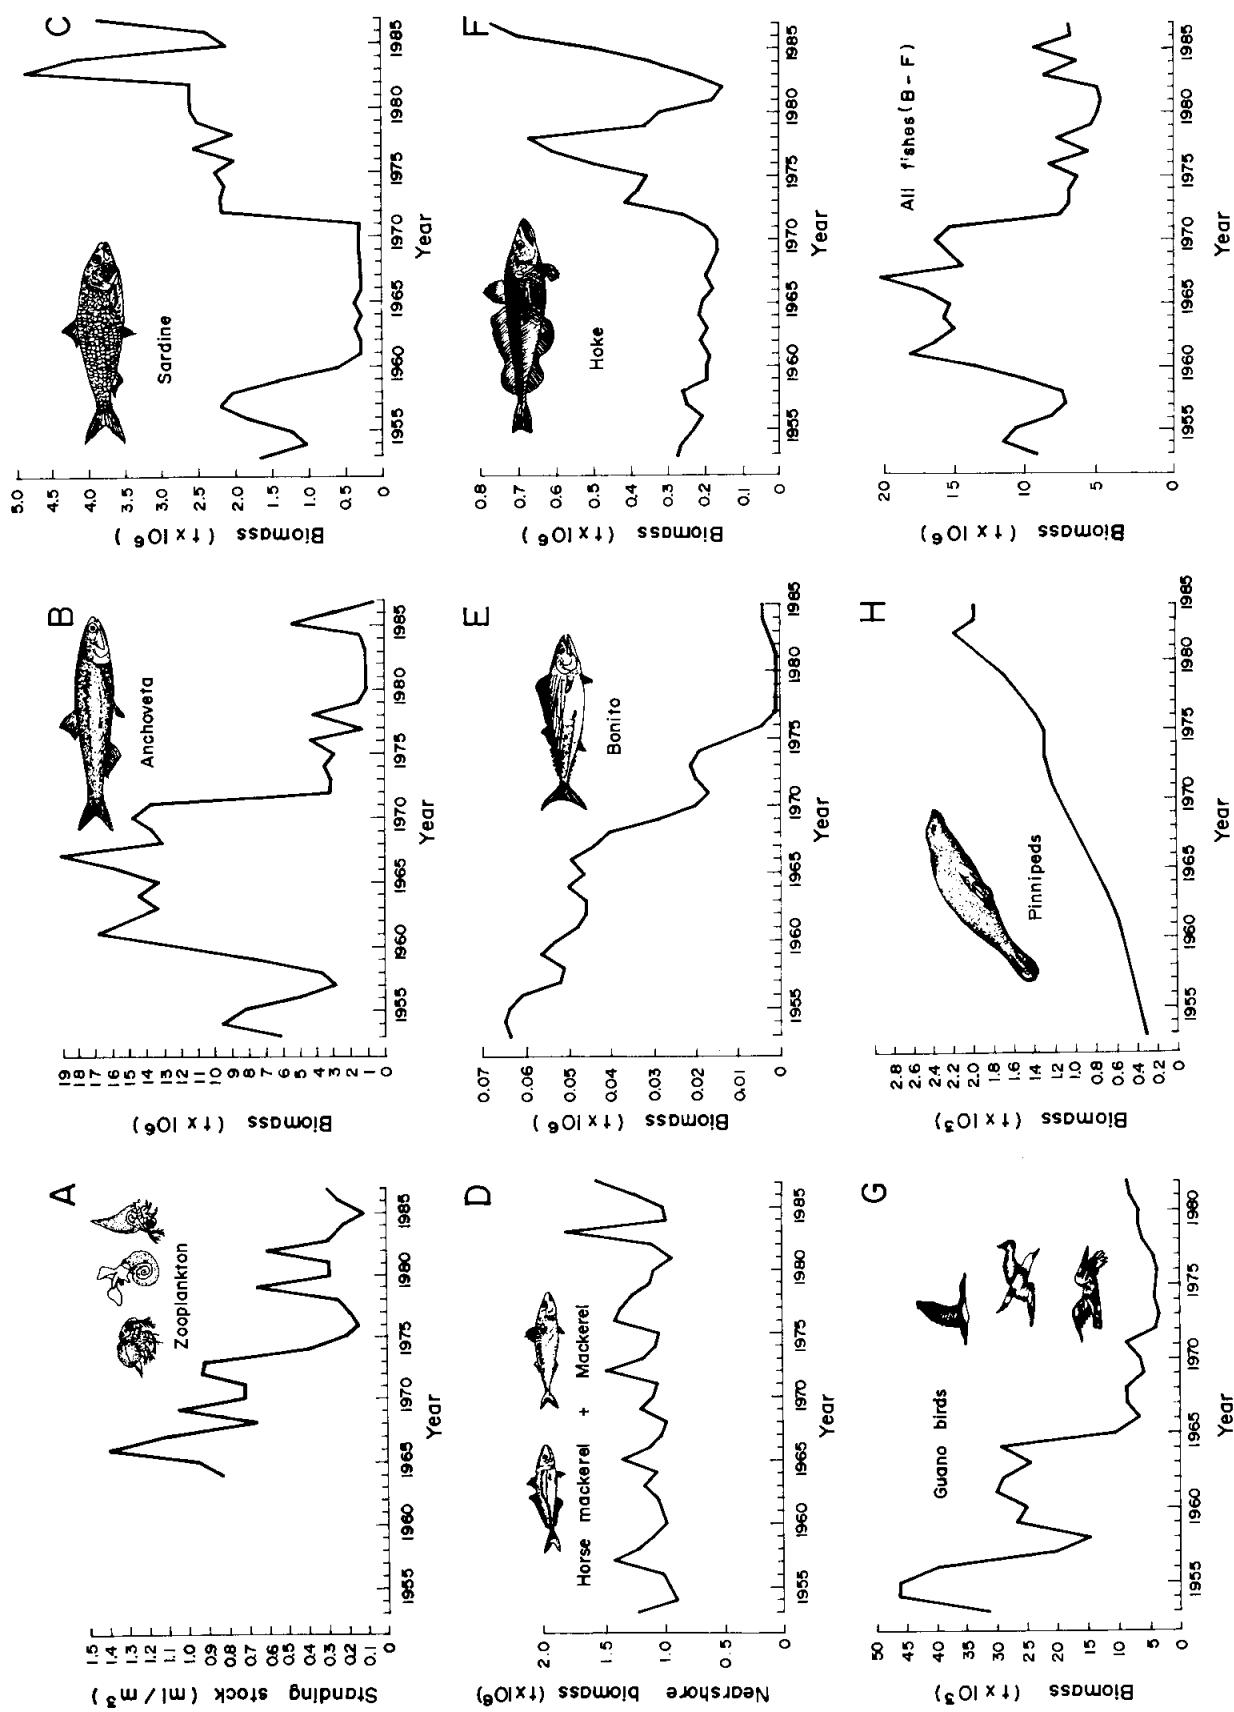

Fig. 1. Mean annual biomass of major species/groups (A-H) in the main anchoveta distribution area, 4-14°S (see Table 1).
 Fig. 1. Biomasa promedio anual de las especies/grupos (A-H) más importantes en el área principal de distribución de la anchoveta, 4-14°S (ver Tabla 1).

Major Trends

Before 1975, the Peruvian pelagic fishery was aiming almost exclusively at anchoveta, due to the ease with which anchoveta-derived products (oil, fish meal) could be marketed outside of Peru. The size of the fleet of purse seiners ("bolicheras") aiming at anchoveta roughly reflects the catch trends: a rapid increase from less than 100 units in 1953 to 1700 in the early 1970s; then following the 1971/72 collapse of anchoveta recruitment, a rapid decrease occurred in the early 1980s (the more recent trend is again increasing).

Fig. 1 illustrates the change in biomass of some major species in the MAR. This figure includes three types of plots:

- (i) plots with increasing trend,
- (ii) plots with no clear trend, and
- (iii) plots with decreasing trend.

Fig. 2 compares the mean initial biomass (1955-1965) with the (1975-1985) biomass in terms of their relative changes, by species/groups. The two extremes are bonito and pinnipeds; with the former decreased by a factor of 17, while the latter increased by a factor of 3.

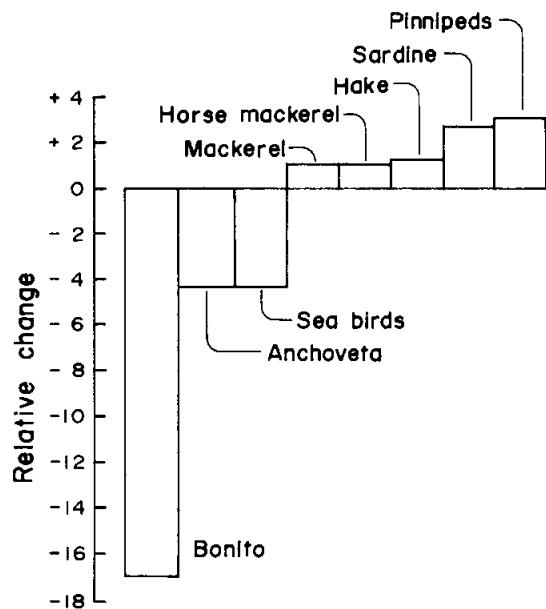

Fig. 2. Relative change in biomass of major species/groups in the main anchoveta distribution area, comparing the period 1955-1965 with the period 1975-1985.

Fig. 2. Cambio relativo en biomasa de las principales especies/grupos en el área principal de distribución de la anchoveta.

Fig. 1 also summarizes our scanty knowledge on zooplankton biomass off Peru, i.e., on one of the key elements of the ecosystem (see Carrasco and Lozano, this vol.). Although "ml/m³" is probably not the best index of total abundance, the data at hand indicate a clear, declining trend: zooplankton biomass during the 1980s is only about 25% of what it was in the 1960s.

Generally, the available oceanographic time series are characterized by marked interyear variations, El Niño-related anomalies (Fig. 3) as by strong seasonal cycles (see Brainard and McLain 1987). Long term increasing trends have been observed for offshore SST and offshore Ekman transport, velocity, turbulence and upwelling off Callao.

Overall the Peruvian waters are on the average 2°C warmer today than 30 years ago and water mixing and transport processes are more intensive than in the past. The consequences of these changes for evolutionary adaptations of life cycles, strategies and processes are largely unknown, although some general inferences can be made. Thus, a temperature increase, for example, will increase the turnover rate of all organisms, and favor a shift in species composition toward warm-adapted forms.

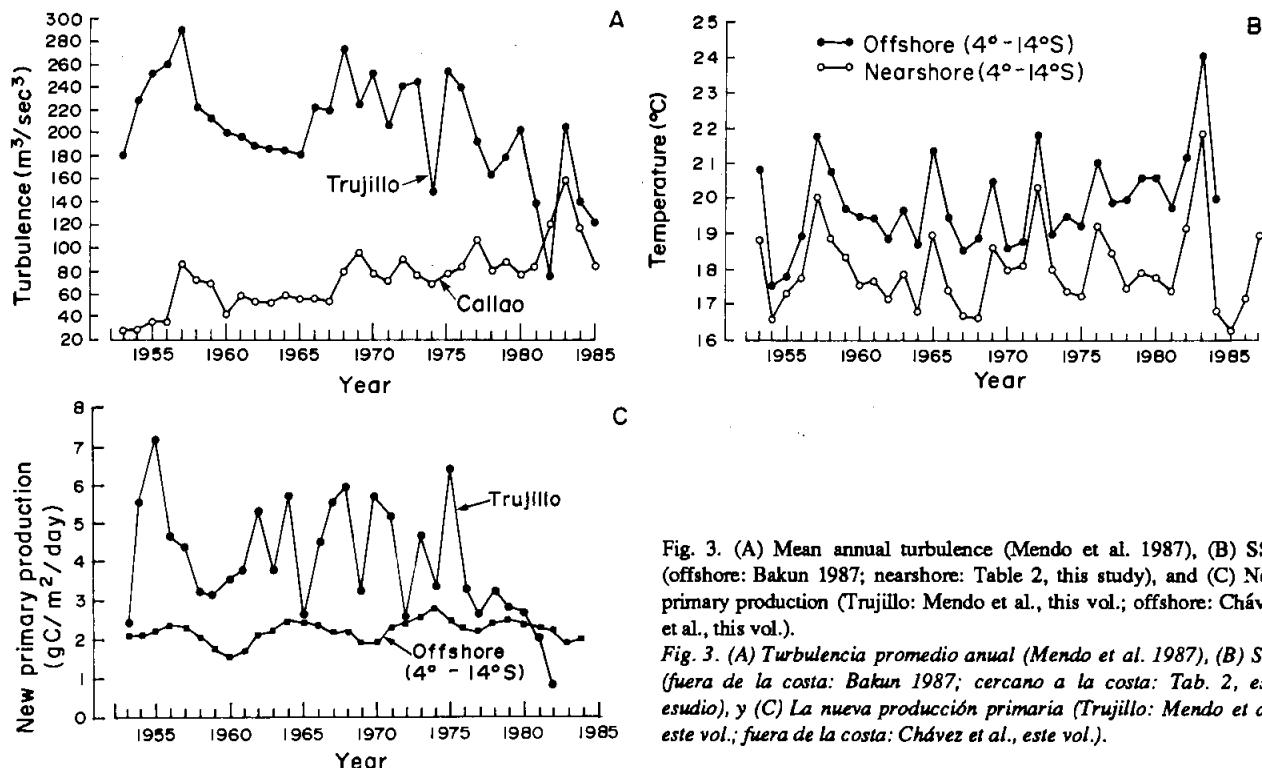

Fig. 3. (A) Mean annual turbulence (Mendo et al. 1987), (B) SST (offshore: Bakun 1987; nearshore: Table 2, this study), and (C) New primary production (Trujillo: Mendo et al., this vol.; offshore: Chávez et al., this vol.).

Fig. 3. (A) *Turbulencia promedio anual* (Mendo et al. 1987), (B) *SST fuera de la costa*: Bakun 1987; cercano a la costa: Tab. 2, este estudio, y (C) *La nueva producción primaria* (Trujillo: Mendo et al., este vol.; fuera de la costa: Chávez et al., este vol.).

The observed change of various oceanographic parameters has also resulted in the reduction of some gradients. Thus upwelling and turbulence, which were previously different off Callao and Trujillo, have now become very similar in value (Mendo et al. 1987).

This long-term "flattening" of gradients within the MAR might have important implication for fishes of various life stages. What is good for larvae (low turbulence, upwelling of offshore transport = stable food patches, low drift mortality) is not necessarily good for the adults, because it corresponds to low primary and secondary production (Navaluna and Pauly 1986; Pauly 1987). Thus, the chance for organism, particularly larvae, to find (or to occur at) the optimal "spot" along a gradient may nowadays be lower than earlier.

Change in the Growth Patterns of Individual Fishes

During the 1970s and 1980s, anchoveta grew faster, and reached larger sizes than during the 1950s and 1960s (Palomares et al. 1987 and see Fig. 4A). These authors suggested that the decline of anchoveta biomass enhanced the individual growth of anchoveta, i.e., that growth was originally density-limited. Recent studies (Fig. 4B) also suggest density-dependent effect on sardine, albeit in opposite direction. This is reasonable in view of the recent surge of biomass in this species.

Shifts in Species Dominance

Two cases of species replacements (Daan 1980) or at least of shifts in species dominance occurred in the Peruvian ecosystem in the last decades.

A clear shift of species dominance occurred among the guano birds. In the 1980s and early 1960s, cormorants represented over 80% of the guano birds of Peru; when total bird numbers

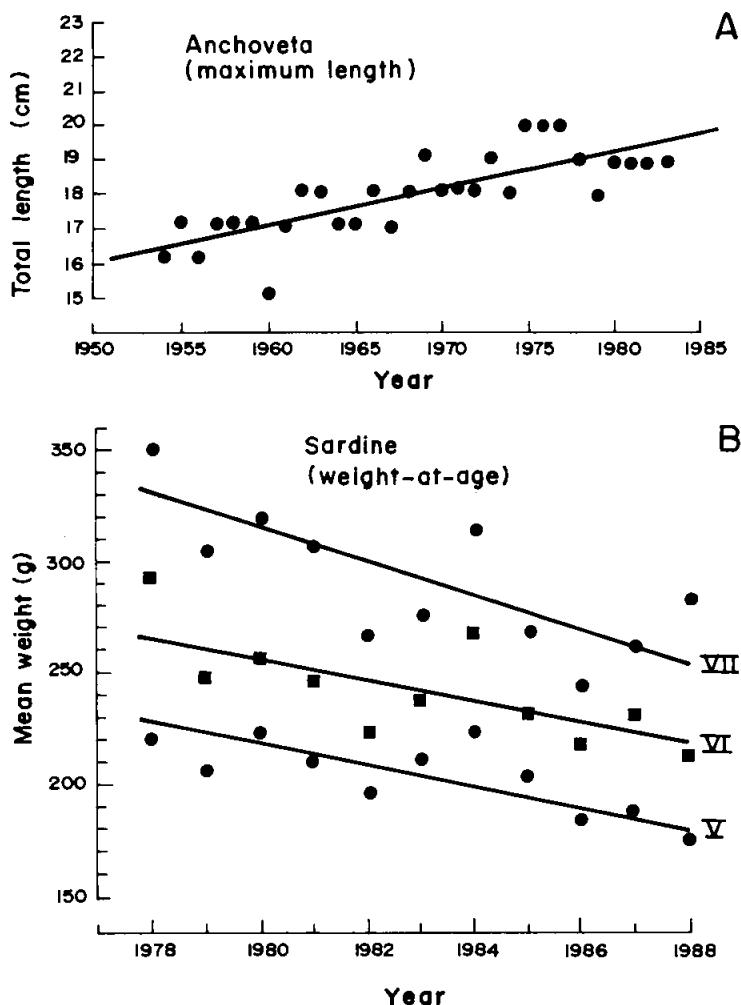

Fig. 4. (A) Changes in the maximum length of anchoveta, and (B) the weight-at-age of adult sardine. (Sardine data courtesy of Dr. A.C. Burd and Mr. J. Zuzunaga).

Fig. 4. (A) Cambios en la longitud máxima de anchoveta y (B) el peso a la edad de sardina adulta. (Datos de sardina cortesía del Dr. A.C. Burd y Sr. J. Zuzunaga).

were reduced by the anchoveta fishery, boobies experienced a relative increase, and became dominant in 1972, a situation which lasted until the late 1970s (Tovar et al. 1987).

Another better-known example is the partial replacement of anchoveta by sardine (see Fig. 1), which is based on mechanisms discussed in Ursin (1980) and Muck et al. (1987). Mutual predation on eggs and larvae between anchoveta and sardine should have comparable effects on both stocks. However, detailed analysis of filtering rates shows that anchoveta have a gape 4.4 times larger than sardine of the same size. Also, the growth efficiency of anchoveta is higher than that of sardine (Villavicencio and Muck 1983a), a consequence of difference in the swimming mode of the two species (Weihs 1974). Hence, anchoveta should usually have a greater impact on sardine than *vice versa*. This would explain the near permanent dominance, of anchoveta in geological time, (De Vries and Pearcy 1982) and identify the fishery as the key factor for the altered dominance pattern prevailing to date.

The third example to be presented here of changes in species dominance involves the relationship between anchoveta and hake. The contribution of Espino and Wosnitza-Mendo (this vol.) suggests that high anchoveta biomass correlate with low hake biomass. Negative interactions between hake and anchoveta are further illustrated in Sandoval et al. (this vol.), where high hake larvae densities are shown to correlate negatively with high anchoveta biomasses.

Anchoveta thus influence the biomasses of both their competitors (sardines) and at the least one of their predators (hake). Strong reduction, through fishing, of the anchoveta biomass thus had a strong impact on dominance patterns.

Shifts in Feeding/Fishing Strategy

Changes in diet composition reflecting changes in anchoveta availability were found in fur seals and sea lions, with sardine replacing anchoveta (Majluf 1985). Similarly, mackerel and horse mackerel shifted to zooplankton when anchoveta became scarce (Fig. 5). The latter shift, together with the increase of sardine (a zooplankton feeder) may be the reason for the decreasing trend of zooplankton (c.f. Fig. 1).

The purse seiners fleet, in analogy to the anchoveta predator also shifted from its former unique "prey" to a mixture of sardine and anchoveta as the anchoveta declined. In fact, the drop in catch per effort which the purse seiners experienced in from 1972 to 1974 (Fig. 6) can be attributed to the time it took for the fleet to switch to its new "prey" (sardine).

Population Dynamics of Anchoveta

The El Niño events which occurred off Peru since 1953 (i.e., in 1953, 1957-1958, 1965, 1969, 1972-1973, 1977, 1982-1983 and 1987) have all affected the biomass of anchoveta (see Fig. 7B). However, anchoveta population growth is usually high following such event and it appears that whatever El Niño events "do" to the anchoveta, it has no-long term consequence,

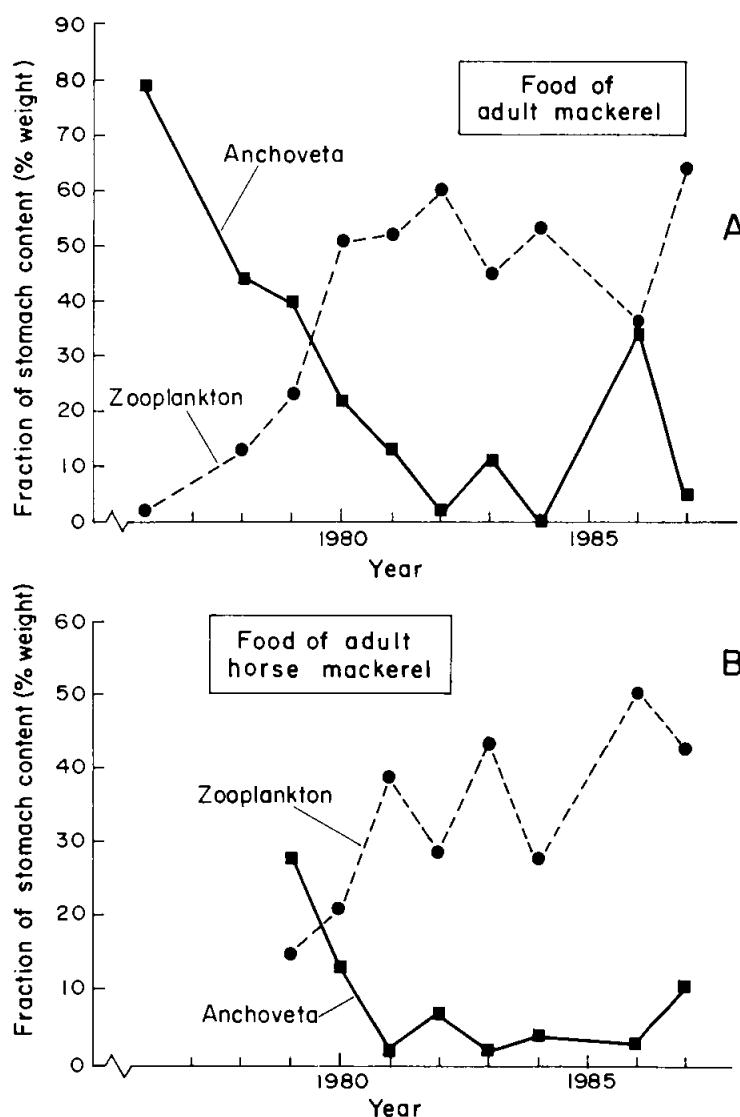

Fig. 5. Changes in diet composition of adult (>30 cm) mackerel (A) and horse mackerel (B).

Fig. 5. Cambios en la composición de la dieta de adultos de caballa (A) y jurel (B) (>30 cm).

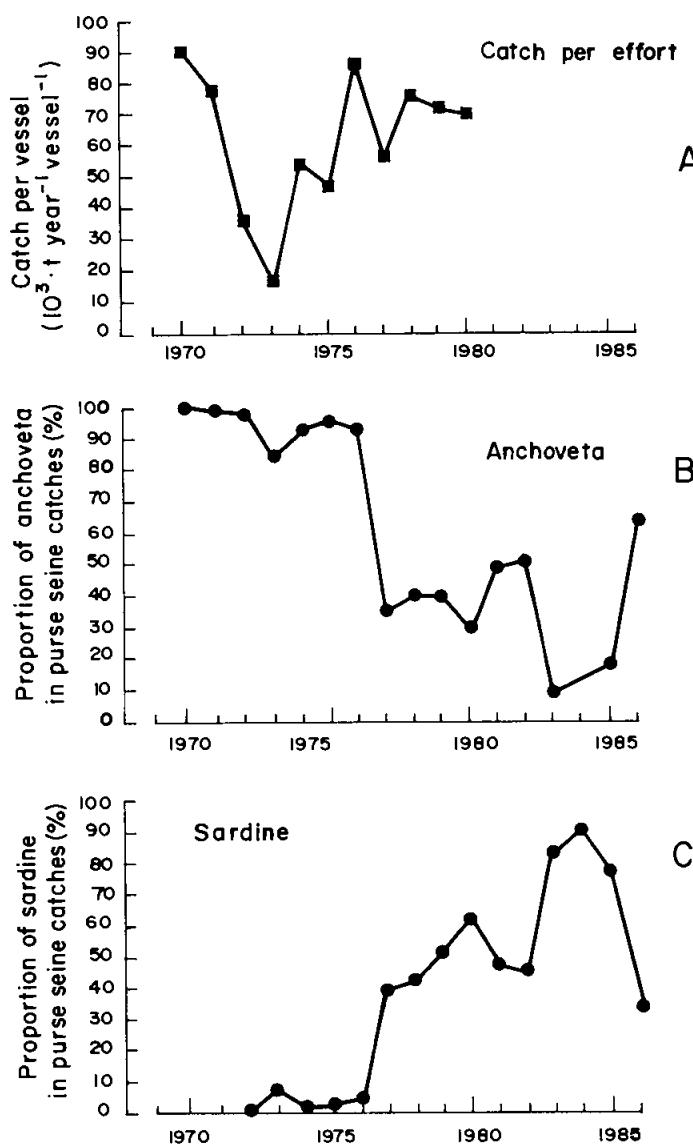

Fig. 6. (A-C) Changes in catch per effort and catch composition in the Peruvian pelagic fishery.

Fig. 6. (A-C) Cambios en la captura por unidad de esfuerzo y en la composición de capturas en la pesquería pelágica peruana.

because biomass losses are rapidly compensated for, at least in the absence of a fishery (see below).

It is nowadays generally assumed that it was the combined effects of a strong fishery plus El Niño events which control anchoveta population dynamics and that a combination of effects was responsible for the collapse, in 1972-1973 of anchoveta recruitment and biomass. The continuously increasing trend of anchoveta exploitation even after the 1972-1973 collapse (Fig. 7C) suggests that it was mainly the fishery which prevented a recovery of anchoveta biomass in the 1970s. However, the available time series also show that a moderately strong fishery does not preclude an increase of anchoveta biomass: during the period for 1958 to 1961, anchoveta catches increased from 1 to $5 \text{ t} \times 10^6$ within two years while anchoveta biomass increased from 4 to $17 \times 10^6 \text{ t}$. A similar situation also occurred for 1965 to 1967 when catches were increasing from 7 to $10 \times 10^6 \text{ t}$ while anchoveta biomass increased from 13 to $19 \times 10^6 \text{ t}$, and from 1982 to 1985, when catches increased from 0.1 to $0.8 \times 10^6 \text{ t}$ while anchoveta biomass increased from about 1 to $6 \times 10^6 \text{ t}$.

Much earlier work on the dynamics of the Peruvian anchoveta was based on the assumption that the guano birds were the major predators of anchoveta (Jordan 1967, Schaefer 1970; Murphy 1972; Furness 1982). However, the studies in Pauly and Tsukayama (1987), notably those of Pauly et al. (1987a), Muck and Sánchez (1987) and Muck and Pauly (1984) show that

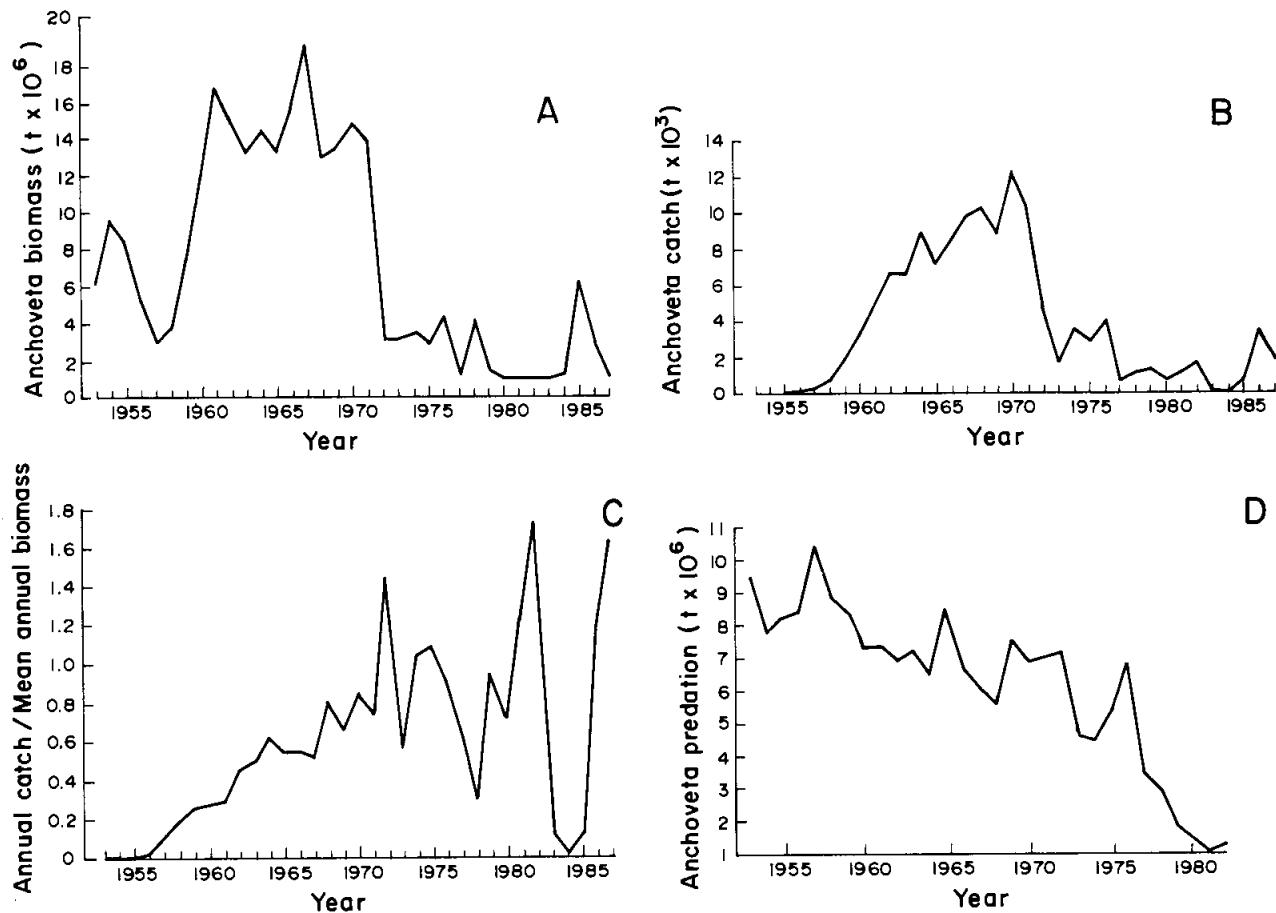

Fig. 7. Anchoveta biomass (A) and the parameters influencing it: catch (B), El Niño (C), predation (D).

Fig. 7. Biomasa de la anchoveta (A) y los parámetros que la influencian: captura (B), El Niño (C), predación (D).

teleosts, especially horse mackerel *Trachurus murphyi* consume far more anchoveta than the guano birds, and *ipso facto* also more than the pinnipeds (see Pauly and Palomares, this vol.). Indeed, horse mackerel predation exceeded fishery catches throughout the 1950s and in the mid 1970s as well (see Muck and Sanchez 1987). Thus, studies of the population dynamics of anchoveta must consider fish predation if they are to lead to useful management advice.

Table 3 summarizes the results of matches between changes in anchoveta biomass (+ or -) with changes of other parameters hypothesized to be linked (causally or otherwise) to anchoveta biomass.

Some of the significant matches in Table 3 are straightforward to explain, i.e., one should expect a relationship between changes in anchoveta biomass and fishery catches. Other matches are more difficult to explain, e.g., that between anchoveta biomass changes and upwelling off Trujillo. The Northern/Central stock of anchoveta has a distribution and spawning area expending over more than 1000 km, and it is surprising that its biomass changes should be so closely correlated with local upwelling.

The data of Table 3 support the hypothesis that offshore transport has a negative effect on anchoveta (Bakun 1987). Mendelsohn and Mendo (1987) showed, on the other hand, that neither upwelling nor turbulence correlated directly with anchoveta recruitment. They concluded that "Lasker events" (i.e., 4-day periods of reduced turbulence) do not have, in the Peru system, the positive effect on engraulid recruitment which they appear to have along the California coast (Peterman and Bradford 1987). Overall, the question of the impact of wind-driven processes (i.e., turbulence, upwelling, offshore transport) is in need of further work.

Table 3. Test results of matches between (i) time series of anchoveta biomass and (ii) another time series.^a

Tabla 3. Resultados de pruebas comparativas entre (i) series de tiempo de biomasa de anchoveta y (ii) otra serie de tiempo.

| Time series tested (ii) | Years used for comparison (n) | Chi-square | Hypothesis rejected ($P < 0.05$) |

| Sardine biomass ^d | 31 | n.a. ^d | yes ^d |

^aTime series used here are documented in Tables 1 and 2 and/or above in the text; the hypothesis tested was that the +, ++ and +++ pairs are normally distributed (see Materials and Methods section). The critical chi-square value was 3.84 for 1 d.f.

^bFrom Chávez et al. (this vol.).

^cFrom Mendo et al. (this vol.).

^dSardine biomass was here estimated as an inverse function of anchoveta biomass. Hence χ^2 value is inflated.

The significant correlation between interannual changes of anchoveta biomass and SST probably does not indicate any direct effect. Rather, temperature mediates the distribution of mackerel and horse mackerel (Muck et al. 1987), which prey heavily on anchoveta when their distribution area overlap (Muck and Sánchez 1987), and recent biomass estimates obtained during 1983-1987 using echoacoustics confirm the SST-driven model used by Muck and Sánchez (1987) to estimate anchoveta consumption by mackerel and horse mackerel.

Thus overall, it does appear that anchoveta mortality, as controlled by the pelagic fishery and anchoveta predators plays the crucial role in anchoveta dynamics. These considerations allow the identification of three periods since the onset of the anchoveta fishery in 1953, 1958 to 1960, 1961-1971 and 1972-1987, documented in Table 4.

The data in this table confirm that the increasing and decreasing interannual changes of anchoveta biomass are largely due to changes in mortality, themselves due to fishing and predation. Table 4 also documents how in the mid 1960s the pelagic fishery replaced horse mackerel as a major source of mortality for anchoveta.

Interestingly, no correlation was found between interannual changes of anchoveta biomass and guano birds, although one should expect the guano birds to depend strongly on anchoveta production.

The probable explanation for this is that the sea birds are affected more by changes in vulnerability (an SST-mediated variable) than by changes of anchoveta biomass itself (Muck and Pauly 1987).

One can expect the sea birds depending on anchoveta to be also mediated via the fishery catches and by fish predation; this all suggests that comparison of signs of the biomass changes in two time series may not be the appropriate approach in the case of the guano birds.

Predator-Prey Disequilibrium

The anchoveta predators in the Peruvian upwelling system (see Fig. 8) may be grouped as follows:

| Opportunists | Specialists |
|----------------|-------------|
| mackerel | cormorant |
| horse mackerel | booby |
| sea lion | pelican |
| fur seal | bonito |
| hake | |

The purse seiners exploiting anchoveta can also be identified by these two categories: with regard to their capacity, they reacted to changes of anchoveta abundance like the opportunist

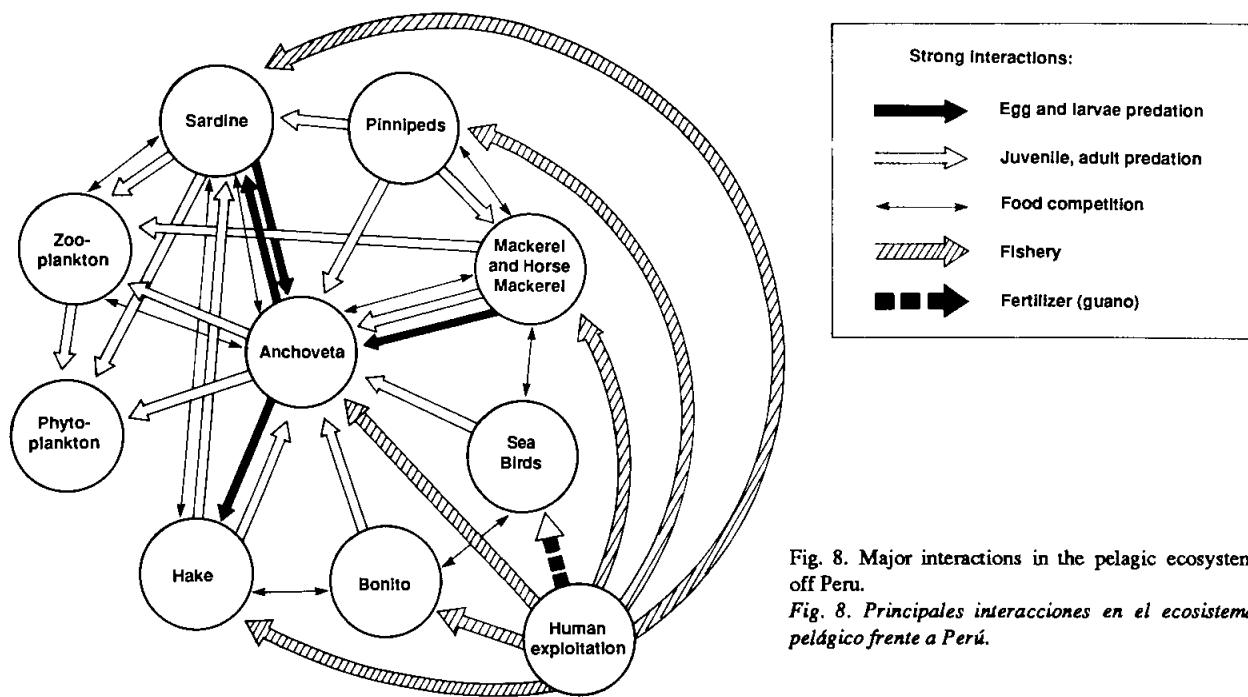

Fig. 8. Major interactions in the pelagic ecosystem off Peru.

Fig. 8. Principales interacciones en el ecosistema pelágico frente a Perú.

predators, i.e., they increased. With regard to their numbers, however, the purse seiners declined in reaction to changes of anchoveta abundance, just as the specialists did (see Table 2, and data in Agüero 1987).

As a result, the present sum of predation + harvesting capacity is equal to what it was in the 1960s, although anchoveta has now only one fourth of the biomass it then had. Or put differently: the total annual capacity of the Peruvian upwelling ecosystem to "consume" anchoveta is about 5 times the average biomass, vs one time in the 1960s.

This again means that the pressure on the anchoveta stock is nowadays much higher than in the past. This disequilibrium suggests that, overall, the anchoveta may have difficulties regaining its past high biomasses.

Still, the experience of 1985 is encouraging: after a period of extremely low biomasses (1980-1983, see Fig. 1B), biomass estimates based on two independent approaches (echo acoustics and the egg production method) indicated a dramatic increase. Detailed analysis of the context makes this understandable:

- from 1983 to 1985 the catch/biomass ratio of anchoveta was low (Fig. 7C),
- mackerel and horse mackerel biomass within the MAR - and hence anchoveta predation - were extremely low in 1984-1985 (Fig. 9), a consequence of the abnormally low SST, and
- low temperatures allowed anchoveta to disperse into a larger habitat (see Muck et al, this vol.), thus reducing density dependent checks on anchoveta growth.

In other words, the period between the 1982/83 El Niño event and 1985 was the most favorable for anchoveta since the collapse of 1971/72.

The response of the Peruvian purse seiner fleet to the 1984/85 increase of anchoveta biomass was to drastically increase the exploitation of this fish, which resulted in 1987 having one of the highest annual catch/biomass ratios ever recorded off Peru (see Fig. 7C).

This excessive level of effort, combined with the reoccurrence of the high SST associated with the weak El Niño of 1987 and hence of large quantities of mackerel and horse mackerel within the MAR predictably reduced anchoveta back to their present low level.

To summarize the preceding paragraphs on the population dynamics of anchoveta, we thus note:

- the fishing and predation mortality of anchoveta can be straightforwardly expressed as function of fishing effort, anchoveta vulnerability (and predator biomass in the case of

- predation); fishing and predation mortality largely determine the extent (if any) of anchoveta population growth;
- ii) high SST impacts anchoveta directly (e.g., by reducing habitat size) and indirectly (by creating appropriate conditions for the invasion of the coastal waters by anchoveta predators (see Fig. 9). High SST occur in summer and especially during El Niño events;
 - iii) reduction of habitat size increase the vulnerability of anchoveta to purse seiners (see also Csirke, this vol.);
 - iv) the high SST brought about by El Niño events also impact anchoveta via a variety of biological mechanisms such as: increase of (density-dependent) egg and larval cannibalism, increase of metabolic costs, food scarcity, etc.;
 - v) thus, the SST-mediated distribution patterns of anchoveta and of its predators largely determine the dynamics of anchoveta, and the ultimate fate of the fishery (Fig. 10).

It is now obvious that the Peruvian pelagic fishery failed to account for these interrelationships and this explains both the crucial 1971-1972 collapse, and the non-recovery of the stock thereafter.

This makes the human factor the decisive one, and strengthens the argument for an ecosystem-oriented management scheme.

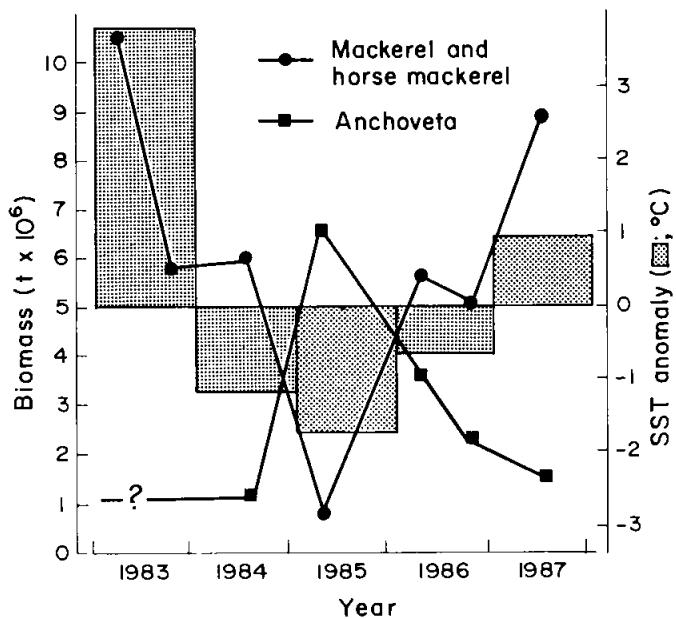

Fig. 9. Mean annual SST-anomalies (bars) and biomass estimates (acoustic surveys) of anchoveta, mackerel and horse mackerel.
Fig. 9. Promedio anual de las anomalías de TSM (barras) y estimaciones de biomasa (evaluaciones acústicas) de la anchoveta, caballa y jurel.

Options for Management

Comparison of the present biomass of the six major species in the Peruvian ecosystem with those of the 1960s shows a deficit of 10 million tons, i.e., the Peruvian fishing industry has now at its disposal only half of the reserves it has 30 years ago, when the Peruvian population was half its present size. The data presented above strongly suggests that the reduction of the biomass of harvestable fish in the Peruvian sea is the result of overfishing, or more precisely, of a lack of synchronization of the fishing with periods of high anchoveta production.

The same data also suggest, however, that the present knowledge on the dynamics of anchoveta is sufficient to design a rational exploitation strategy. Such strategy would be based on the observation that the anchoveta stock can recover after a collapse if conditions are "favorable". Favorable conditions occur if fishing pressure is low and predation pressure is low.

Reducing the predation pressure on anchoveta involves applying a high fishing pressure on anchoveta predators, notably horse mackerel and mackerel. Exploiting these species at the right time is straightforward because these species move inshore when SSTs are high.

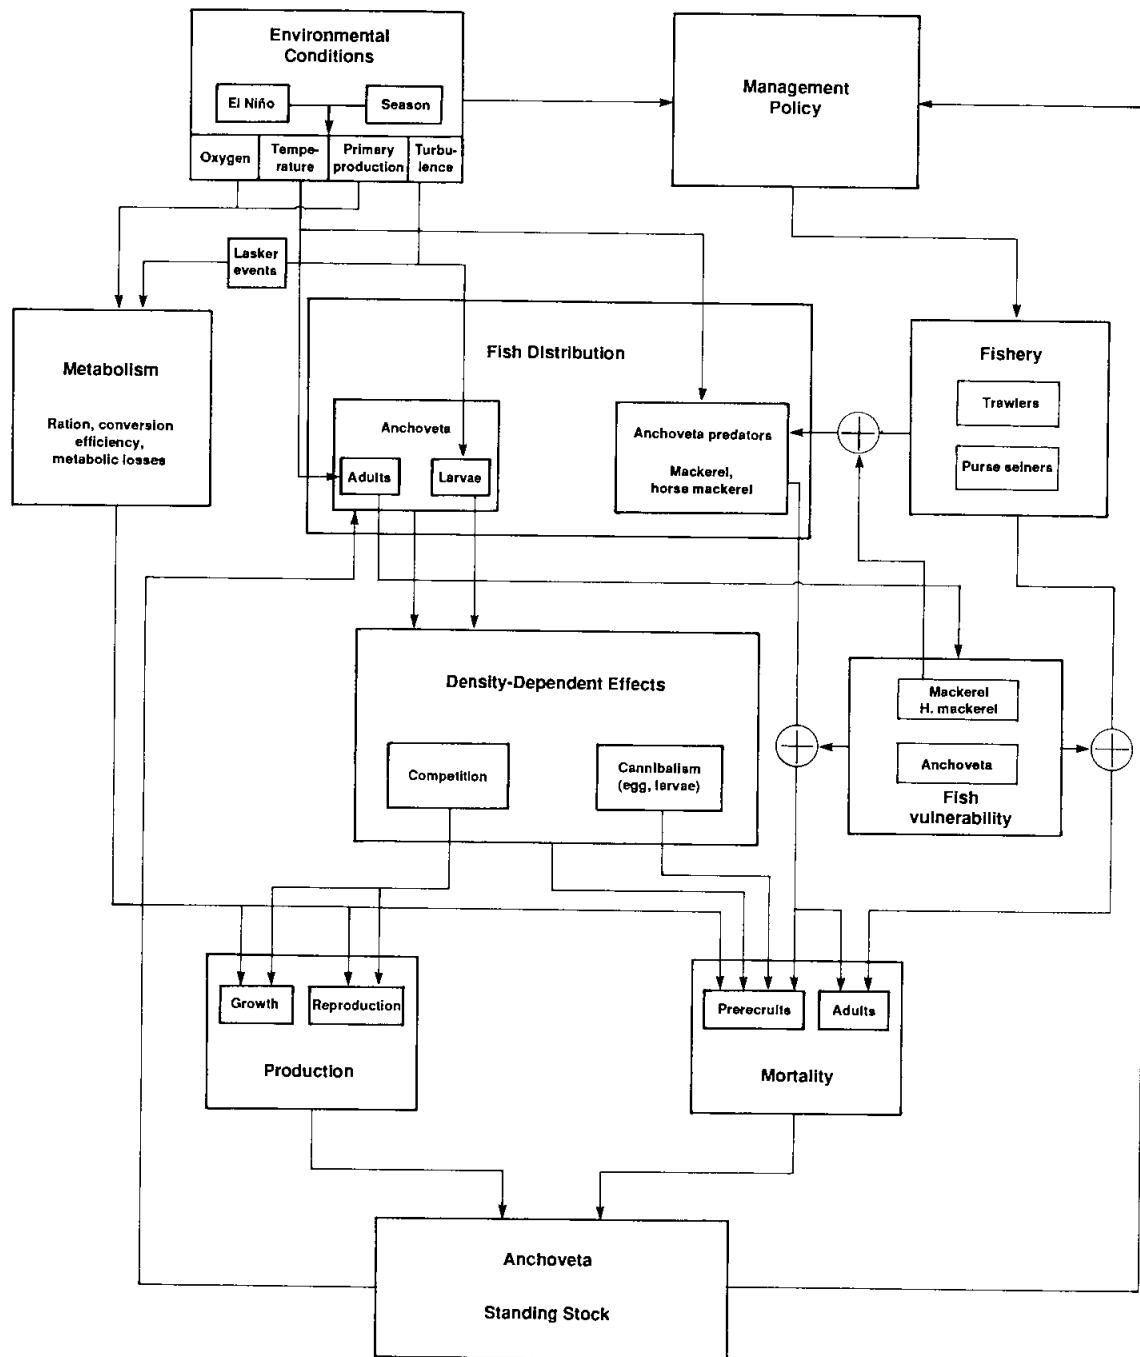

Fig. 10. Schematic representation of the guiding mechanisms and feedback loops which can affect anchoveta population size and fishery.

Fig. 10. Esquema de los mecanismos guías y enlaces de la retroalimentación que pueden afectar el tamaño poblacional y la pesquería de la anchoveta.

A rational exploitation scheme for the multispecies stock off Peru would thus involve an alternance between exploitation of anchoveta (when biomasses of anchoveta are high and SST are low) and of horse mackerel and mackerel (when SST are high).

The species composition of the multispecies complex off Peru provides three different options for the fisheries sector:

- production of fish meal and fish oils
- production of fish for direct human consumption
- some mixture of (i) and (ii)

Option (i) prevailed until the 1971/72 collapse and is now discredited, option (ii) being now declared government policy. However, use of pelagic fishes for direct human consumption (e.g., via canning or (iced) fresh fish) is still very much less than use of anchoveta (and sardine) for fish meal and oils.

The main reason for this gap between stated policy and the present reality is the fact that fish meal can be easily marketed internationally, and that its price tends to increase, while domestic marketing of mackerel, horse mackerel and hake is hampered by low market prices relative to harvesting costs and the absence of an efficient cold chain along the Peruvian coast and into the hinterland.

Thus, option (ii), meant to help solve the protein deficiency of low-income Peruvians (the overwhelming majority of the population), can probably not be implemented without subsidies.

Option (iii) is proposed here as alternative: profits realized by Pesca-Perú, the state fishing enterprise from fish meal exports could be used to gradually acquire the capacity to economically harvest and market mackerel and horse mackerel. This would reduce predation pressure on the anchoveta, of which more would then become available for fish mean production. All data reviewed above suggest that such positive feedback loop could be made to contribute to the rehabilitation of the Peruvian fisheries.

Acknowledgements

The author wishes to thank Mr. H. Tovar for providing the sea bird abundance data for 1984-1987 in Table 1, Dr. G. Sánchez and Miss M. Céspedes for their cooperation in the data analyses on diet composition of mackerel and horse mackerel in Fig. 5, Dr. A.C. Burd and Mr. J. Zuzunaga for providing the sardine weight-at-age data in Fig. 4b, and Mr. C. Aranda for his assistance with data processing.

Abstract

The interrelationship of the various contributions in this volume are briefly reviewed as are some errors in this volume's predecessor. Some aspects of the modelling work presently underway on the Peruvian upwelling system are presented.

Resumen

Las inter-relaciones entre las diversas contribuciones en éste volumen son brevemente revisadas al igual que algunos errores en el precesor a éste volumen. Se presentan además, algunos aspectos del trabajo de modelación actualmente en desarrollo acerca del sistema de afloramiento peruano.

Introduction

The book of which this is the last contribution represents the proceedings of the "International Workshop on Models for Yield Prediction in the Peruvian Upwelling Ecosystem", held at the Instituto del Mar del Perú, Callao, Perú, 24-28 August 1987, and the first contribution, by Csirke et al., presents the report of this workshop.

This book, however, includes more contributions than those which were prepared for presentation and formally presented at the said workshop. It also includes a paper that was conceived and essentially written during the workshop (Mendo et al., this vol.) in response to one of the formal presentations, as well as a number of papers that could be written only after the workshop was held. This applies particularly to the reestimation of anchoveta monthly biomasses from 1953 to the 1980s (Pauly and Palomares, this vol.) and of their reproductive output and egg mortality (Pauly and Soriano, this vol.). The former analysis could be performed only after the anchoveta consumption by hake had been estimated for that same period (Muck, this vol.), which itself could be estimated only after the available estimates of the biomass of hake of Northern/Central Peru had been extended from the last decades all the way back to 1953 (Espino and Wosnitza-Mendo, this vol.). In other words, this book presents a collection of closely integrated papers, of which the majority use time series data either derived or also considered in other contributions. Combined with the fact that the bulk of the contributions included here deals with *change*, this explains the subtitle of this book: "Dynamics and Interactions".

*ICLARM Contribution No. 560.

The aim of the above-mentioned workshop was to examine whether sufficient information exists on the Peruvian upwelling system for a simulation model of that system to be developed which would be usable for purposes of fisheries management.

The answer was a guarded "Yes". Yes, because the predecessor of this volume (Pauly and Tsukayama 1987) considered a "formidable collection of papers" by one reviewer, indeed presented a vast amount of data in both raw and analyzed forms - enough to provide the basis for a serious modelling effort. This was a *guarded* "yes" however, because a large fraction of the variability of the physical components of the Peruvian upwelling system have the characteristics of an unpredictable "random walk" (Bohle-Carbonell, this vol.). Still, it is apparent that the anchoveta population off Peru is capable of stabilizing its biomass despite environmental variability. In fact, the consensus that emerged is that it is mainly the purse seine fishery which, in concert with predators such as the horse mackerel *Trachurus picturatus murphyi* (see Parrish, this vol.), nowadays prevents the anchoveta from reestablishing itself to the high levels prevailing, e.g., in the 1960s (see Muck's contribution on trends from the early 1950s to mid 1980s, this vol.).

Previous simulation models of the Peruvian ecosystem, notably that of Walsh (1975), emphasized primary and secondary production, and nutrient recycling, while giving scant attention to the species composition and biomass variability of the exploited fishes (anchoveta, sardine, mackerel, horse mackerel, bonito, etc.) of that system, not to speak of the guano birds and sea mammals (see also Walsh 1981).

Explicit consideration, in a simulation model of the Peruvian ecosystem, of the fishes and higher vertebrates requires that the various rates affecting their dynamics be precisely estimated; this pertains to growth and mortality rates, food consumption rates, etc. Hence, we have included contributions on some rates (e.g., the growth and food consumption rates of anchoveta) already considered in this book's predecessor, but reestimated them, using improved methods and/or new data (see e.g., contributions of Morales-Nin and of Pauly et al., this vol.).

We are well aware that none of the contributions included in this book and its predecessor, nor the planned modelling exercise, could make full use of all the information available from the Peruvian upwelling system (especially those on anchoveta, see Jarre et al., this vol.). For this reason, we document in Appendix I of this book a collection of fourteen 5 1/4" MSDOS diskettes (for IBM PC and compatible microcomputers) which contain all the time series and other data upon which the contributions in this book and its predecessor are based. Interested colleagues are invited to request copies of these diskettes from ICLARM, which is authorized to distribute them (for a small fee) throughout the world.

This form of data exchange is quite new; we hope it will contribute to the reestablishment of an important principle of science - now seriously endangered by massive databases analyzed with undocumented software - i.e., that the readers of a paper should be able to reproduce the results included in that paper *both in principle and in practice*.

We assume, obviously, that a wide dissemination of these data will encourage their further analysis, and hence will eventually benefit Peru, e.g., through elucidation of the mechanisms which determine the variable level of her fisheries resources. A recent contribution by Cury and Roy (1989), based on data presented in this book's predecessor, illustrates the process we have in mind here.

Another principle of science which is often neglected is the explicit correction of known errors in one's earlier publications. In this book, two chapters provide corrections for important errors in three earlier contributions (Table 1). I fear that while some will appreciate this information as an improvement to the book to which they refer, some others will feel that the existence of such errors - corrected or not - reduces the value of the previous book, and perhaps of this as well. Clearly, what we have here is a case of not being able to please all at the same time (see also Fig. 1).

As suspected by Cushing (1988), the data in this volume and its predecessors are presently being used for multispecies modelling. This proceeds along two lines of inquiries:

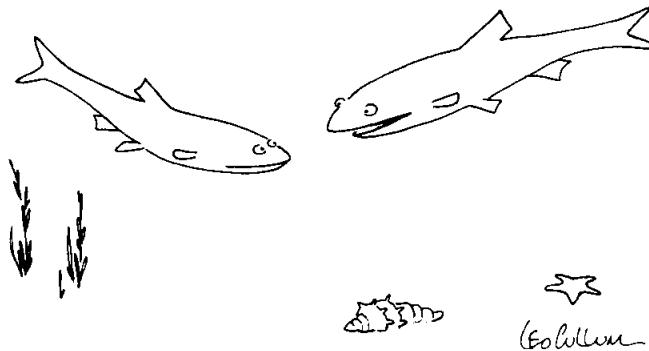

- construction of a successive steady-state model covering relatively short periods during which the Peruvian upwelling system maintained identifiable states (e.g., early to mid-1960s or mid- to late 1970s).

Table 1. Some errors in contributions included in Pauly and Tsukayama (1987).^a
Tabla 1. Algunos errores en las contribuciones en Pauly y Tsukayama (1987).

| Error | Author, page and exhibit no. | Remedy |
|--|--|--|
| Programming error in estimating wind stress on sea surface | Bakun (1987, Figs. E, F and G) | See Bakun and Mendelsohn (this vol.) |
| Numerous erroneous values due to misalignment of entries | Santander (1987, Table 3) | Corrections included in Table 2 of Pauly and Soriano (this vol.) |
| Underestimation ^b of anchoveta egg mortality | Pauly (1987, p. 329-330, equation (4), Table 2 and Fig. 4) | See Pauly and Soriano (this vol.) |

^aThis table does not cover the various misspellings and unimportant typographical and other errors that may be found upon close reading of this book.

^bInterestingly, Cushing (1988) suggested that anchoveta egg mortality may be overestimated.

“Some will love you, son, and some will hate you.
 It’s always been that way with anchovies.”

Fig. 1. *Algunos te amarán hijo, y otros te odiarán. Siempre ha sido así con anchovetas.*

- development of a simulation model of the Peruvian upwelling ecosystem, in which key processes are expressed through coupled differential equations, parameterized using the rate estimates time series and other data presented in this volume and its predecessor. The first of these approaches, presently emphasized by Ms. A. Jarre, is intended to serve two major aims:
 - i) estimating, for various time periods the average biomass and/or production of elements of the system for which these characteristics are not available;
 - ii) linking up the studies conducted to date on the Peruvian upwelling system with the theory of ecosystem phenomenology developed by Ulanowicz (1986), as initiated in Pauly (1987, Table 1).
- The second modelling approach, emphasized by Dr. P. Muck, is both time- and space-structured: the Peruvian upwelling ecosystem has been divided up into nearly 200 squares, whose (SST-mediated) suitability for anchoveta, sardine, horse mackerel and other fishes is reassessed on a monthly basis and into which a purse seiner fleet can be deployed. The catch of

the fleet is then modelled, for each square fished, as a function of the biomass of various fish species which are themselves functions of the previous fishing and environmental regimes.

This approach, which is reminiscent of earlier work by Sharp (1979), is documented in Muck et al. (1989) and Jarre et al. (1989), where the abovementioned steady-state approach is also presented. Software and documentation for these models will become available in 1990, and readers may write to the author for information on this.

In conclusion, I wish to thank on my behalf and on behalf of my co-editors, the many colleagues and other friends who have made this book, and the workshop upon which it is based, possible, particularly:

In Peru, Messrs. Jaime Sobero and Rogelio Villanueva, present and former Executive Directors of IMARPE, respectively, for their support of PROCOPA and of cooperation with ICLARM; Ms. Blanca Rojas de Mendiola and A. Alamo, for contributing their valuable databases on anchoveta; to all PROCOPA and IMARPE staff, who may not be individually acknowledged in the various contributions of this book, but whose input is nevertheless appreciated.

In the Federal Republic of Germany, Drs. M. Bilio and W. Schmidt, for their unflagging support of PROCOPA and of its cooperative linkages with ICLARM.

In the USA, Dr. Izidore Barrett, Director, South-West Fisheries Center, NMFS, La Jolla, and Dr. A. Bakun, Chief, Pacific Fisheries Environmental Group, NMFS, Monterey for their support of interactions between our groups.

And in the Philippines, to Ms. Letty Dizon, ICLARM Managing Editor, to ICLARM draftsmen Ovidio Espiritu, Jr., Christopher Bunao and Albert Contemprate, to Mr. Victor Sambilay, Jr. and to the secretary of the senior editor, Ms. Josie Cañezo, for their immense contribution toward the completion of this volume.

Appendix I

Documentation of Available 5 1/4' MSDOS Data Diskettes on the Peruvian Upwelling Ecosystem^a

The set of 14 diskettes presented below contains the bulk of the data used for or derived in the various contributions in the books "The Anchoveta and its Upwelling Ecosystem: Three Decades of Change" (Pauly and Tsukayama 1987) and its sequel, "The Peruvian Upwelling Ecosystem: Dynamics and Interactions" (this vol.). Diskettes 1-5 contain files created using the LOTUS 1-2-3 program. Diskettes 6-8 contain the egg maps presented in Santander (1987) and 9-10 contain monthly summaries of Santander's maps, documented in Senocak et al. (this vol.). Both sets of maps are presented in the form of DIASHOW picture files. The diskettes numbered 11-13 contain a DBASE III+ file combining the data compiled by Rojas de Mendiola (this vol.) and Alamo (this vol.). Finally, diskette 14 contains a preliminary bibliography of anchoveta *Engraulis ringens* created by Jarre et al. (this vol.) using the Microsoft WORD processor program. (Diskette 14 is not discussed further below.)

All files were created with IBM compatible (MSDOS) microcomputers. The worksheet files created in LOTUS 1-2-3 have the extension ".WK1". The picture files, created for the DIASHOW graphics software have the extension ".PIC"; the DBASE III+ file, on the other hand, has the ".DBF" as extension name, while the bibliography file has ".DOC" as its extension name. Brief descriptions of the contents of these files are presented in the following paragraphs.

Diskette 1: Abiotic Factors

Diskette 1 contains the file called ABIOTICS.WK1 with information on physicochemical parameters of the Peruvian upwelling ecosystem. These were assembled from data presented by several authors as time series covering various periods from 1948 to 1989, but generally from 1953 to 1982.

Information on sea surface temperatures (SST) are given from a total of 9 shore stations along the coast of Peru (4°34'S to 17°38'S), based on various sources (see Table 1). Of the data taken from Muck et al. (1989), only those which represented actual observations were included, i.e., values estimated by interpolation or regression (see Muck, this vol.) were omitted.

Further time series related to upwelling are provided on the following upwelling-related parameters: turbulence, wind velocity, turbulence indices, Lasker events (for definition see Mendelsohn and Mendo (1987, footnote to Table 1) and Pauly (1989), upwelling indices, thermocline depth, offshore transport velocity (i.e., the quotient of Ekman transport and thermocline depth), Southern Oscillation Index, solar radiation, cloud cover, Rossby radius and, finally, nitrate concentrations and primary production estimates derived from the models presented in this volume. Table 1 gives a list of the headings in the LOTUS worksheet ABIOTICS.WK1 with more details on the parameters presented above, their units as well as the references to the papers from which each parameter was taken.

Diskette 2: Anchoveta Catch and Related Data

This diskette contains only one file named ANCHOV1.WK1. The bulk of this file consists of a time series, covering the period 1953 to 1987, of percent length-frequency data per centimeter length class, adapted from Tables 1-30 of Tsukayama and Palomares (1987) and Tables 1-5 of Pauly and Palomares (this vol.). Also included are data on the monthly total catch of the fishery in tonnes as well as anchoveta condition factors (c.f.) for those months in which they could be computed from catch samples (i.e., c.f. values estimated from SST are not included).

^aPrepared by M.L. Palomares, A. Jarre and V. Sambilay, Jr., International Center for Living Aquatic Resources Management, MC P.O. Box 1501, Makati, Metro Manila, Philippines.

^aThese monthly mean wind velocity data are means of daily means, themselves based on 8 observations per day. These original observations are available, along with their associated directions (in degree), also for Callao, for the years 1953 to 1982 in the form of ASCII files on twelve 360 K 5 1/4" diskettes for MSDOS computers, from Mr. Jaime Mendo, c/o IMARPE, P.O. Box 22, Callao, Perú.

^bµM = millimole.

Diskette 3: VPA Estimates of Anchoveta Biomass

This diskette consists of two files, ANCHOV2.WK1 and ANCHOV3.WK1. The former, ANCHOV2.WK1, contains monthly biomass estimates, by cm length class, for the Peruvian coast from 4-14°S, as obtained through the VPA III routine of the Compleat ELEFAN program package, and which were presented, for the years 1953 to 1982,

in Tables 5 to 33 of Pauly et al. (1987). This file also includes information on the total anchoveta biomass per month and the number of 3-month old fish recruited to the fishery. The estimated biomass of the parent stock, the estimated biomass of the mature females in the population and the number of eggs produced per month by the mature individuals in the population are also included, as estimated by Pauly and Soriano (1987). All biomass estimates are expressed in metric tonnes while recruitment and egg output are both expressed as number $\times 10^9$ (i.e., in billions).

ANCHOV3.WK1 contains similar information except that this pertains to the reestimation of the total biomasses and of mature anchoveta presented in Pauly and Palomares (this vol.), and Pauly and Soriano (this vol.), respectively. Also, the catch and catch composition time series were updated to July 1987 based on more recent data (see Pauly and Palomares, this vol., and description of contents of diskette 2).

Diskette 4: Data on Predators and Predation

This diskette contains the file called PREDAT.WK1 which consists of time series data covering the period 1953-1982 on monthly abundance and/or biomasses of the major predators and their consumption of anchoveta. The major predators included are bonito, hake, mackerel and horse mackerel, three species of guano birds and two species of pinnipeds. Also included in the file are time series data from 1953 to 1985 on monthly anchoveta biomass as estimated from VPA III by Pauly and Palomares (this vol.). The time series of monthly nominal catch data in 1953-1982 from Tsukayama and Palomares (1987) and in 1983-1987 from Pauly and Palomares (this vol.) were included in this file such that any colleague interested in computing mortality caused by each predator does not need to use any other diskette. Three estimates of natural mortality, i.e., total (M), baseline (M_0) from Pauly et al. (1987) and baseline (M_0) from Pauly and Palomares (this vol.) are also included here (see Table 2 for details).

Table 2. Contents of file PREDAT.WK1 on the Peruvian upwelling system.^a

Tabla 2. Contenido del archivo PREDAT. WK1 en el sistema de aforamiento peruano.

| Headings | Units | Source |
|--|-----------------|---|
| Date | month-year | |
| Anchoveta biomass | t | Pauly and Palomares (1989, Table 8) |
| Bonito biomass | t | Pauly et al. (1987, Table 6) |
| Anchoveta consumption by bonito | t/month | Pauly et al. (1987, Table 13) |
| Cormorant numbers | $N \times 10^6$ | Tovar et al. (1987, Table 3) |

| Anchoveta consumption by cormorants | t/month | Muck and Pauly (1987, Table 6) |
| Boobies numbers | $N \times 10^6$ | Tovar et al. (1987, Table 4) |
| Boobies biomass | $10^3 t$ | Muck and Fuentes (unpub. data) |
| Anchoveta consumption by boobies | t/month | Muck and Pauly (1987, Table 7) |
| Pelican numbers | $N \times 10^6$ | Tovar et al. (1987, Table 5) |
| Pelican biomass | $10^3 t$ | Muck and Fuentes (unpub. data) |
| Anchoveta consumption by pelicans | t/month | Muck and Pauly (1987, Table 8) |
| Sea lion biomass | t | Muck and Fuentes (1987, Table 7) |
| Total food consumption by sea lions | t/month | Muck and Fuentes (1987, Table 7) |
| Anchoveta consumption by sea lions | t/month | Muck and Fuentes (1987, Table 8) |
| Fur seal biomass | t | |
| Total food consumption by fur seals | t/month | Muck and Fuentes (1987, Table 8) |
| Anchoveta consumption by fur seals | t/month | Muck (1989, and unpub. data) |
| Mackerel abundance in MAR | t | Muck and Sánchez (1987, Table 13) |
| Anchoveta consumption by mackerels | t/month | Muck (1989, and unpub. data) |
| Horse mackerel abundance in MAR | | Muck and Sánchez (1987, Table 14) |
| Anchoveta consumption by horse mackerel | t/month | Espino and Wosnitza-Mendo (this vol., Table 3); Muck (1989: seasonal values, interpolated by month) |
| Hake abundance | $N \times 10^3$ | Muck (1989, Table 4) |
| Anchoveta consumption by hake | t/month | Tsukayama and Palomares (1987, Tables 1-30) |
| Anchoveta nominal catch | t/month | Pauly and Palomares (1989, Fig. 7) |
| Anchoveta total natural mortality (M) | year | Pauly et al. (1987, Table 3) |
| Anchoveta baseline natural mortality (M_0) | year | Pauly and Palomares (1989, Table 7, with interpolations) |
| Anchoveta baseline natural mortality (M_0) | year | |

^aThis file also contains the fishing effort data in Table 3 of Csirke (this vol.).

Diskette 5: Information on Egg Maps and Egg Mortality

This diskette consists of four files, namely: EGNUM.WK1 and EGGMAPS.WK1. The first file, EGNUM.WK1, summarizes the data on anchoveta egg surveys presented in Santander (1987) for the period 1964-1985. This file also includes derived statistics from Table 2 of Pauly and Soriano (this vol.) such as the daily reproductive output expressed as number of eggs ($N \times 10^{12}$), the biomass (in $t \times 10^6$) of the anchoveta parent stock and of the sardine population, the anchoveta egg development time (in days) and observed and predicted total egg mortality (Z , day). Note that the column in the spreadsheet labeled "midmonth" represents the month on which the center of the sampling survey period fell.

The second file, EGGMAPS.WK1, contains a detailed analysis, per half degree square of the egg standing stocks off Peru obtained from Santander's (1987) egg survey maps as performed by Senocak et al. (this vol.). The file is organized such that the column headings indicate the dates of each survey (from start to finish) with their corresponding "midmonths" (the same as the "midmonths" in EGNUM.WK1, see above) and the map numbers (in Santander 1987). The rows refer to the different half degree squares (see Fig. 1 in Senocak et al., this vol.); the cells give the egg standing stock estimates of each half degree square. Note that the coordinates of each square are expressed both in terms of degrees (longitude and latitude) and as vertical and horizontal code numbers (i.e., X-axis and Y-axis codes, see Fig. 1 in Senocak et al., this vol.). The following two conventions were used throughout the spreadsheet: (1) 0.00 means that the half degree square in question was sampled but that no eggs were found; and (2) -9 means that the half degree square containing this value was not sampled at all.

Diskettes 6-10: Picture Files of Egg Maps

These diskettes contain a program called DIASHOW.EXE and picture files which allow for a graphics display of Santander's egg survey maps. Diskettes 6-8 contain the picture files of the original 90 egg survey maps as presented in Figs. 3 to 25 of Santander (1987), while diskettes 9-10 contain the picture files of the mean monthly anchoveta egg distributions presented in Fig. 6 of Senocak et al. (this vol.) as derived from the original 90 egg survey maps. Please note that the DIASHOW.EXE program runs only on a HERCULES or compatible graphics card.

It should also be noted that, in order to access the graphics from diskettes 6-8, the contents of all three diskettes must first be copied onto a hard disk sub-directory. Then go into this subdirectory and view the maps by typing DIASHOW LIST at the C> prompt. The program will ask for the user to press either the spacebar to continue viewing or "e" to exit.

The monthly egg maps in diskettes 9 and 10 were arranged into two groups of 12 each, one for the period 1964-1971 (diskette 9) and the other for 1972-1986 (diskette 10). Thus, in order to view the egg maps for 1964-1971, type DIASHOW LIST1 at the A> prompt with diskette 6 in drive A; to view the maps for 1972-1986, type DIASHOW LIST2 with diskette 7 in drive A.

DIASHOW will then require that the user presses the spacebar to continue or to press "e" to exit the program. The next screen shows a title page in German which is here translated as:

**Simulation
of the egg distribution of *Engraulis ringens*
off Peru
in two year groups (1964-1971, 1972-1986)**

then, press the spacebar to go to the next screen which shows

**1.
Year group
(1964-1971)**

Pressing the spacebar again gives on screen the "climatological" average map for the month of January and so on until the last map for the month of December. Typing DIASHOW LIST2 with diskette 7 in drive A will put on screen the maps for each month of the second year group. Note that pressing "e" at any time while the DIASHOW program runs will abort its execution and bring the user back to the A> prompt.

Diskettes 11-13: The Anchoveta Database

The information available on the food and feeding and reproduction of anchoveta in the raw data sheets of Rojas de Mendiola (this vol.) and Alamo (this vol.) were used to create one DBASE III Plus database, consisting of 28 fields and 9,735 records in total. Each record represents one single specimen of anchoveta.

A detailed description of the fields is given in Table 3. For the coding system of the available information see Rojas de Mendiola (this vol.), Alamo (this vol.) and Pauly et al. (this vol.). Missing information in the raw data sheets were generally coded with -9 in the database, except for the fields describing the food items of anchoveta: empty records for the latter (six) fields were coded as "0". If only qualitative information on anchoveta eggs in the stomach was available, this information was coded as "-9" in the "ancheggs" field. In this case, "0" refers to observation of zero anchoveta eggs in the stomach.

Table 3. Definition of data fields in the Rojas/Alamo anchoveta database.

Tabla 3. Definición de campos de datos en la base de datos para anchoveta Rojas/Alamo.

| Field no. | Name | Field description | Minimum | Value | Maximum | Number of values > 0* | Remarks |
|---|------------|--|---------|-------|---------|-----------------------|--|
| Information on sampling location | | | | | | | |
| 1 | SAMPLENO | Sample number as stated in raw data sheets | 1 | 9,260 | 9,735 | | |
| 2 | S-DAY | Day of sampling | 1 | 31 | 9,678 | | |
| 3 | S-MONTH | Month of sampling | 1 | 12 | 9,725 | | |
| 4 | S-YEAR | Year of sampling | 1,953 | 1,982 | 9,725 | | |
| 5 | S-TIME | Time of sampling | 9 | 2,400 | 7,665 | | |
| 6 | DEG-S | Latitude position of sample (in degrees) | 4.5 | 19.4 | 9,527 | | Midnight = 2,400 Generally: central points of Marsden squares |
| 7 | DEG-W | Longitude position of sample (in degrees) | 70.5 | 82.5 | 9,258 | | |
| 8 | TEMP | Sea surface temperature (in °C) | 12.5 | 25.6 | 7,471 | | |
| Biological information on fish sampled | | | | | | | |
| 9 | LENGTHMM | Total body length (in mm) | 30 | 201 | 9,782 | | SL converted to TL if necessary (Tsukayama and Palomares 1987) |
| 10 | WEIGHTGR | Total body wet/weight (in g) | 1.1 | 57.9 | 6,630 | | |
| 11 | GUTMM | Length of the digestive tract (in mm) | 13 | 460 | 2,396 | | |
| 12 | STOMCONTGR | Weight of the stomach content (in g) | 0 | 5.7 | 6,966 | | |
| 13 | EVISWTGR | Body weight of gutted fish (in g) | 0.9 | 44.2 | 2,055 | | |
| 14 | GONADWTGR | Weight of the gonads (in g) | 0.01 | 1.29 | 1,166 | | |
| 15 | VISCERFAT | Amount of fat surrounding the intestines | 0 | 3 | 4,604 | | See Alamo (this vol.) for scale |
| 16 | DIGESTAGE | Stage of digestion of the stomach content | 0 | 1 | 3,678 | | |
| 17 | FULLNESSGA | Fullness index of the gastric part of the stomach | 0 | 1 | 4,905 | | See Rojas de Mendiola (this vol.) for scale |
| 18 | FULLNESSPY | Fullness index of the pyloric part of the stomach | 0 | 1 | 3,576 | | |
| 19 | GONADSTAGE | Maturity stage of the gonads | I | VII | 6,115 | | |
| 20 | SEX | Sex of fish | 0 | 1 | 7,003 | | Females 0 - 3,361 records; Males 1 - 3,642 records |
| Information on ingested food* | | | | | | | |
| 21 | ZF | "Zooplankton Fraction": percent of zooplankton in diet | 0 | 100 | 6,416 | | |
| 22 | ANCHEGGS | Number of anchoveta egg in the stomach | 1 | 319 | 1,178b | | |
| 23 | FOOD-1 | Food items in the stomach | 1 | 14 | 6,530 | | |
| 24 | FOOD-2 | Food items in the stomach | 1 | 14 | 5,711 | | |
| 25 | FOOD-3 | Food items in the stomach | 1 | 14 | 4,872 | | |
| 26 | FOOD-4 | Food items in the stomach | 1 | 14 | 2,092 | | |
| 27 | FOOD-5 | Food items in the stomach | 1 | 14 | 336 | | |
| 28 | FOOD-6 | Food items in the stomach | 1 | 14 | 31 | | |

*For fields no. 22-28, the numbers refer to values > 0.

bIn this field, "-9" means some eggs were present, but their number is not known.

For coding of the sampling positions, the center of the squares used for locating samples in the raw data sheets (see Fig. 1 in Rojas de Mendiola, this vol., and Fig. 2 in Alamo, this vol.) was taken as representative of the whole square and re-expressed in degrees latitude (S) and longitude (W). Erroneous entries for the sampling location were adjusted longitudinally when they resulted in sampling "on land".

Single stomach fullness observations in the raw data sheet were taken as referring to the gastric part of the stomach; when two entries for stomach fullness occurred, the first was recorded as pertaining to the gastric part, and the second, to the pyloric part. Maturity stage "VII" (recuperating), as given in the original data sheets, was set to stage "II", which thus represent either (smaller) "immature" or (larger) "recuperating" specimens. Missing entries in the sea surface temperature field ("temp") were completed using temperature values of the same sampling month, year and at the same sampling position when available. For inshore data, filling of gaps was performed based on monthly means SST values in Rojas de Mendiola (1958), Zuta and Urquiza (1972), Zuta et al. (1983), Zuta et al. (1984), Brainard and McLain (1987), Senocak et al. (this vol.), Tsukayama (this vol.), or based on three-month means (Urquiza et al. 1987). For offshore data, filling of gaps was achieved by extrapolation of inshore temperatures according to the inshore-offshore temperature gradient off Chimbote.

A number of "logic-checks" were then performed on the database in order to detect biologically inconsistent entries. Details are provided in Table 4. First of all, range checks were performed for each field. Then, obvious relationships between two fields were checked (e.g., if the weight of the stomach content is "0", the digestion stage of the stomach content must be "-9"). Finally, some numerical relations between two or more fields were examined: their ratio (e.g. the gonadosomatic index) was calculated, their frequency distribution examined for outliers, and these were set to "-9" in the database.

Table 4. Details on quality and logic checks of entries in the Rojas/Alamo anchoveta database.

Tabla 4. Detalles acerca de la calidad y verificaciones lógicas en la base de datos de Rojas/Alamo sobre anchoveta.

| No. | Condition | Changes if conditions not met |
|-----|---|---|
| 1 | LENGTHMM < 210 | Whole record excluded |
| 2 | WEIGHTGR > 60 | WEIGHTGR set to -9 |
| 3 | STOMCONTGR = 0 --> FULLNESSGA = 0 or FULLNESSGA = -4 | FULLNESSGA set to -9 |
| 4 | STOMCONTGR = 0 --> FULLNESSPY = 0 or FULLNESSPY = -9 | FULLNESSPY set to -9 |
| 5 | STOMCONTGR = 0 and FULLNESSGA = 0 --> FULLNESSPY = 0 | FULLNESSPY set to 0 |
| 6 | STOMCONTGR = 0 --> DIGESTAGE = -4 | DIGESTAGE set to -9 |
| 7 | STOMCONTGR = 0 --> ANCHEGGS = 0 | STOMCONTGR set to -9 |
| 8 | ZF = 100 --> FOOD-1 ... FOOD-6 ≠ 2 ... 8 | ZF set to -9 |
| 9 | ZF = 0 --> FOOD-1 ... FOOD-6 = 2 ... 8 or FOOD-1 ... FOOD-6 = -9 | ZF set to -9 |
| 10 | IF WEIGHTGR ≠ -9: STOMCONTGR + GONADWTGR + EVISWTGR ≤ WEIGHTGR | Values checked separately, erroneous values set to -9 (missing values set to 0) |
| 11 | IF EVISWTGR ≠ -9: STOMCONTGR + GONADWTGR ≤ EVISWTGR | Values checked separately, erroneous values set to -9 (missing values set to 0) |
| 12 | 0.3 ≤ WEIGHTGR * 100 / (LENGTHMM 10) ³ ≤ 1.2 | WEIGHTGR set to -9 |
| 13 | 20 ≤ GUTMM * 100 / LENGTHMM ≤ 250 | GUTMM set to -9 |
| 14 | 50 ≤ EVISWTGR * 100 / WEIGHTGR < 100 | EVISWTGR set to -9 |
| 15 | 0 ≤ GONADWTGR * 100 / EVISWTGR < 9 | GONADWTGR set to -9 |
| 16 | 0 ≤ STOMCONTGR * 100 / WEIGHTGR < 10 | STOMCONTGR set to -9 |

If the weight of the stomach content was "0", but non-zero entries had been made under the "food items" fields, it was assumed that the food composition had been derived based on examination of other parts of the intestines; also, the "zooplankton fraction" (ZF) was accepted, but not the entries on the digestion stage of the food, as the latter was assumed to pertain exclusively to the condition of food in the stomach.

Table 5 is a facsimile of a sample printout of the database, pertaining to entries nos. 3271 to 3321.

Note that the Rojas/Mendiola database, as described above, can only be run on a hard disk, using the DBASE III+ program (not included here). Run RESTORE (of DOS 3.2) to access the file using the path C:\DBASE\ANCHOVET\ANCHOVET.DBF.

Table 5. Facsimile of a sample printout of the Rojas/Alamo anchoveta database, for entries No. 3271 to 3321 (see also Table 4).

| No. | SAMPLE | DAY | MONTH | YEAR | TIME | DEG_S | DEG_M | TEMP | LENGTH | WEIGHT | (g) | (mm) | STOMACH | EVISUAT | GASTRIC | FULLNESS | GROWD | SEX | IF | ANCHAGES | FOOD_1 | FOOD_2 | FOOD_3 | FOOD_4 | FOOD_5 | FOOD_6 | | |
